ABSTRACT

We analyse the orbital distribution of elliptical (E) and lenticular (S0) galaxies using SAURON integral-field stellar kinematics within about one effective (half-light) radius. We construct the anisotropy diagram, which relates the ratio of the ordered and random motion in a galaxy (V/σ) to its observed ellipticity (ε), for the 48 E/S0 galaxies from the SAURON survey. For a subsample of 24 galaxies consistent with axisymmetry, we use three-integral axisymmetric Schwarzschild dynamical models to recover the detailed orbital distribution, and we find good agreement with the anisotropy derived from the $(V/\sigma, \varepsilon)$ diagram. In a companion paper (Paper IX), we show that the early-type galaxies can be subdivided into two classes of systems with or without a significant amount of specific stellar angular momentum. Here, we show that the two classes have different distributions on the $(V/\sigma, \varepsilon)$ diagram. The slow rotators are more common among the most massive systems and are generally classified as E from photometry alone. Those in our sample tend to be fairly round ($\varepsilon \lesssim 0.3$), but can have significant kinematical misalignments, indicating that as a class they are moderately triaxial, and span a range of anisotropies ($\delta \lesssim 0.3$). The fast rotators are generally fainter and are classified as either E or S0. They can appear quite flattened ($\varepsilon \lesssim 0.7$), do not show significant kinematical misalignments (unless barred or interacting), indicating they are nearly axisymmetric and span an even larger range of anisotropies ($\delta \lesssim 0.5$). These results are confirmed when we extend our analysis to 18 additional E/S0 galaxies observed with SAURON. The dynamical models indicate that the anisotropy inferred from the $(V/\sigma, \varepsilon)$ diagram is due to a flattening of the velocity ellipsoid in the meridional plane ($\sigma_R > \sigma_z$), which we quantify with the β anisotropy parameter. We find a trend of increasing β for intrinsically flatter galaxies. A number of the fast rotators show evidence for containing a flattened, kinematically distinct component, which in some cases counter-rotates relative to the main galaxy body. These components are generally more metal rich than the galaxy body. All these results support the idea that fast rotators are nearly oblate and contain disc-like components. The role of gas must have been important for

†Hubble Fellow.

their formation. The slow rotators are weakly triaxial. Current collisionless merger models seem unable to explain their detailed observed properties.

Key words: galaxies: elliptical and lenticular, cD – galaxies: evolution – galaxies: formation – galaxies: kinematics and dynamics – galaxies: structure.

1 INTRODUCTION

Early-type galaxies are traditionally classified into elliptical (E) and lenticular (S0) galaxies. More than 30 years ago, before observations of the stellar kinematics were available, E galaxies were thought to constitute a homogeneous class of simple oblate systems, with an isotropic velocity distribution, and in which the flattening provided a measure of the galaxy angular momentum (e.g. Gott 1975). S0 galaxies were considered similar to spiral galaxies, containing an isotropic bulge and a disc, but without significant evidence for gas and dust.

The revolution came in the late 70s, when it became possible to extract the stellar kinematics of bright galaxies. To characterize the degree of ordered rotation in galaxies, the anisotropy diagram was introduced, which relates the ratio between the ordered and random motion (V/σ) in a galaxy to its observed flattening (ϵ). The small observed values of V/σ , for a sample of 13 bright E galaxies, were interpreted as evidence that these systems are inconsistent with being oblate systems, close to isotropic and supported by rotation (Bertola & Capaccioli 1975; Illingworth 1977; Binney 1978). As rotation was not needed to flatten the systems, the observations could also be explained by assuming that E galaxies were triaxial and supported by orbital anisotropy (Binney 1976, 1978). The observations were later extended to a sample of 11 fainter E galaxies (Davies et al. 1983) and bulges of nine barred (Kormendy 1982b) and eight unbarred (Kormendy & Illingworth 1982) spiral galaxies. From the resulting compilation of a sample of 50 Es and bulges, over two orders of magnitude in luminosity, it was found that, contrary to the brighter systems, the fainter galaxies and the spiral bulges were rotating fast and their location on the (V/σ , ϵ) diagram was consistent with oblate isotropic rotators (Davies et al. 1983).

It was later discovered that the fast-rotating galaxies also tend to have discy isophotes, while the slow-rotating ones have boxy isophotes (Bender 1988; Bender et al. 1989). One possibility to explain this connection between photometry and kinematics was to assume the fast-rotating galaxies all contained discs seen at various inclinations on top of a spheroidal stellar component (e.g. Rix & White 1990; Rix, Carollo & Freeman 1999). Observations at different scaleheights on edge-on disc galaxies, however, showed that bulges themselves are rotating fast (Kormendy & Illingworth 1982). The slow rotation of the brighter Es could be equally due to either radial or tangential anisotropy. To address this point, van der Marel (1991) used two-integral Jeans dynamical modelling to analyse the compilation of long-slit kinematics of 37 bright Es. He concluded that Es as a class are *radially* anisotropic. This appeared consistent with what had been observed in the outer parts of N -body simulations of collisionless collapse (van Albada 1982). The difference between the different types of spheroidal systems could be explained in the context of galaxy formation as due to the relative importance of gaseous dissipation (Bender, Burstein & Faber et al. 1992).

The whole picture was summarized by Kormendy & Bender (1996) who proposed a revision of the standard photometric classification (Hubble 1936) of early-type galaxies into E and S0. They

suggested that there was a dichotomy between two classes of early-type galaxies: (i) on one side, the bright, boxy, slow-rotating and radially anisotropic E galaxies, with a break between a steep outer surface brightness profile and a more shallow nuclear cuspy core, and (ii) on the other side, the generally fainter, discy, fast-rotating and isotropic discy E and S0, without clear breaks between the outer and nuclear profiles.

More recently, a systematic investigation of the anisotropy of a sample of 21 luminous, nearly round and slowly rotating E galaxies was performed using spherical models by Kronawitter et al. (2000) and Gerhard et al. (2001). They found that ellipticals are only moderately radially anisotropic. Gebhardt et al. (2003) constructed more general axisymmetric models and explored the anisotropy of a sample of 12 early-type galaxies, which included flattened objects. They found a range of anisotropy and no obvious trend (except near the nuclear supermassive black holes), but they also found the roundest galaxies to be generally only weakly anisotropic. However, the models in these studies were generally fitted to the kinematics extracted along a few long-slit positions.

The introduction of panoramic integral-field spectrographs on large telescopes, combined with the advances in the dynamical modelling techniques, has opened the possibility for a reanalysis of the orbital distribution in early-type galaxies. The goal of this paper is to use SAURON (Bacon et al. 2001, hereafter Paper I) integral-field stellar kinematics to derive the (V/σ , ϵ) anisotropy diagram for the SAURON sample (de Zeeuw et al. 2002, hereafter Paper II) in a new way that can be rigorously interpreted with the formalism of Binney (2005). The results are analysed making use of a new classification scheme that we introduce in a companion paper (Emsellem et al. 2007, hereafter Paper IX). The anisotropy derived from the (V/σ , ϵ) diagram is interpreted and tested using general axisymmetric dynamical models for a subsample of the survey galaxies.

The galaxy sample is described in Section 2. In Section 3, we describe the dynamical modelling technique, and in Section 4 we present our modelling results. In Section 5, we present the (V/σ , ϵ) diagram obtained from the SAURON data, while in Section 6 we compare our results with previous works. Finally, in Section 7 we draw some conclusions.

2 SAMPLE AND DATA

Two different subsamples are used in this paper. (i) The main galaxy sample (Table 1) is composed of the 48 E and S0 galaxies of the SAURON survey (Paper II). The (V/σ , ϵ) diagram of this sample is presented in Section 5.2. (ii) For half of the survey galaxies, we constructed axisymmetric dynamical models to interpret the SAURON (V/σ , ϵ) diagram. This modelling subsample of 24 galaxies (Table 2) is the same used in Cappellari et al. (2006, hereafter Paper IV), where we studied the galaxies mass-to-light ratio (M/L).

All the galaxies used have SAURON integral-field spectroscopy out to about one effective (half-light) radius (R_e). The SAURON data were reduced as described in Emsellem et al. (2004, hereafter

Notes. (1) NGC number. (2) Morphological type from RC3. (3) Numerical morphological T-type (LEDA, E: $T \leq -3.0$, S0: $-3.0 < T \leq -0.5$). (4) Effective (half-light) radius R_e measured in the I band from *HST*/WFPC2 + MDM images as described in Paper IV. Comparison with the RC3 values, for the 46 galaxies in common, shows a rms scatter of 20 per cent. (5) Ratio between the maximum radius R_{\max} sampled by the kinematical observations and R_e . We defined $R_{\max} \equiv \sqrt{S/\pi}$, where S is the area on the sky sampled by the SAURON observations. (6) Luminosity-weighted average ellipticity. This was computed from the ellipse of inertia of the galaxy surface brightness inside an isophote enclosing an area $A = \pi R_e^2$, or within the largest isophote fully contained within the SAURON field, whichever is smaller. (7) Luminosity-weighted squared velocity within an ellipse of area A , ellipticity ε and PA given in Column 10, or within the largest similar ellipse fully contained within the SAURON field, whichever is smaller. (8) Luminosity-weighted squared velocity dispersion inside the same ellipse as in Column 7. (9) Luminosity-weighted V/σ ratio within $1R_e$. This is the ratio of Columns 7 and 8 (see equation 10 for a definition of these quantities). (10) Large-scale global luminosity-weighted PA of the photometric major axis. (11) PA of the global kinematic major axis within the SAURON field (direction where $|V|$ is maximum, see text for details). (12) Error in the kinematic major axis of Column 11. (13) λ_{R_e} (see Paper IX) measured within the same ellipse as in Column 7 (about $1R_e$). (14) Galaxy classification from Paper IX: F= fast rotator ($\lambda_{R_e} > 0.1$), S= slow rotator ($\lambda_{R_e} \leq 0.1$).^aThis galaxy is a special slow rotator. It appears axisymmetric and disc like as a fast rotator, but contains two counter-rotating discs (Section 4.5).^bThese two galaxies show nearly face-on bars. The ellipticity is the one of the outer disc, which also defines the photometric PA.

Notes. (1) NGC number. (2) Inclination from Paper IV. (3) Anisotropy parameter β_r , measured in spherical coordinates from the solution of the dynamical models as defined in equation (8). (4)–(6) Anisotropy parameters β , γ and δ determined in cylindrical coordinates from the solution of the dynamical models. The parameters are defined in equations (4) and (5) and equation (2), respectively. (7) Anisotropy parameter δ as measured using the $(V/\sigma, \varepsilon)$ diagram.

Paper III). However, there are some differences between the kinematics presented in Paper III and the one used for this work: (i) to provide a tight constraint to the dynamical models, we extracted the Gauss–Hermite (GH) moments (Gerhard 1993; van der Marel & Franx 1993) of the line-of-sight stellar velocity distribution (LOSVD) up to h_3 – h_6 , using the penalized pixel-fitting method (pPXF; Cappellari & Emsellem 2004); (ii) to measure the mean velocity V and the velocity dispersion σ to be used in the $(V/\sigma, \varepsilon)$ diagram, we did not fit the higher-order GH moments. We verified using pPXF on semi-analytic dynamical models that this generally provides a better approximation to the first and second velocity moment of the LOSVD, which appear in the tensor virial equations from which the $(V/\sigma, \varepsilon)$ diagram is constructed; (iii) to reduce the influence of template mismatch, we updated the library of templates which is fitted together with the kinematics by pPXF. In particular, we constructed the optimal template using the 985 stars of the MILES library (Sánchez-Blázquez et al. 2006), from which ≈ 15 stars are selected by the program to provide a detailed fit to each galaxy spectrum. The use of this new library can reduce the rms scatter in the residuals of the pPXF fit by up to a factor of ≈ 3 , when the spectra have negligible Poissonian noise. One can expect a reduction of the systematic errors in the GH moments by up to the same factor (see fig. B3 of Paper III). In practice, our results are very similar to the ones presented in Paper III, but for some of the most massive galaxies the h_4 values are here significantly lower (see also Shapiro et al. 2006).

Together with the *Hubble Space Telescope*, Wide Field Planetary Camera 2 (*HST*/WFPC2) photometry in the I band, wide-field ground-based MDM photometry (Falcon-Barroso et al., in preparation) is also available for all the modelled galaxies. We used this set of photometric data to parametrize the stellar density distribution in our models according to the multi-Gaussian expansion (MGE) method (Emsellem, Monnet & Bacon 1994; Cappellari 2002). The parameters of the MGE models are given in Paper IV. The MDM photometry was also used to determine the R_e of the sample galaxies.

An additional set of 18 E/S0 galaxies has been independently observed with a similar SAURON setup in the course of various other projects. These objects will be treated as ‘specials’, most having features which motivated a specific observation, and will be only mentioned in Section 5.4 to strengthen the results obtained from the main survey. As in Paper II, the galaxies are classified as either E or S0 from the LEDA morphological type ($T \leq -0.5$; Paturel et al. 2003). The kinematics of these galaxies were not presented in Paper III, and will be presented elsewhere.

3 THREE-INTEGRAL DYNAMICAL MODELLING

The models we study in this paper were presented in Paper IV. The stationary and axisymmetric dynamical modelling technique that we use is based on the Schwarzschild (1979) numerical orbit-superposition method, which was extended to fit kinematical observables (Richstone & Tremaine 1988; Rix et al. 1997; van der Marel et al. 1998). The implementation of the method that we adopt in this paper was optimized for use with integral-field data and is described in Paper IV. Similar axisymmetric implementations were developed by other groups (Gebhardt et al. 2003; Thomas et al. 2004; Valluri, Merritt & Emsellem 2004).

For a given stationary gravitational potential, the stellar dynamics of a galaxy are uniquely defined by the orbital distribution function (DF), which describes the velocities of the stars at every position in the galaxy. As the stellar orbits in a stationary potential conserve at most three isolating integrals of motion, the DF can be written as a function of the three integrals, or any other equivalent parametrization of them. From dimensionality arguments, this implies that the three-dimensional DF cannot be recovered without at least the knowledge of the LOSVD at every spatial position (x', y') on the galaxy image on the sky, which also constitutes a three-dimensional quantity. For an axisymmetric edge-on galaxy, with a *given* potential, this knowledge of the LOSVD seems to be likely sufficient for a unique recovery of the DF, which may not be positive everywhere if the assumed potential is wrong (see section 3 of Valluri et al. 2004). An example of the need for two-dimensional kinematics to constrain the DF is given in Cappellari & McDermid (2005). In Krajnović et al. (2005) and van de Ven, de Zeeuw & van den Bosch (2007), we verified the ability of our implementation of the Schwarzschild method to recover the DF and the internal velocity moments for both two- and three-integral realistic galaxy model, even from incomplete radial coverage.

An implicit assumption of the dynamical models is that the luminosity density, as can be obtained by deprojecting the galaxy surface brightness, provides a good description of the shape of the total density. This is also a key assumption of the $(V/\sigma, \varepsilon)$ diagram. It implies either that dark matter provides a small contribution to the total matter in the regions we study (inside $1R_e$) or that its shape is similar to that of the luminous matter. Evidence from dynamical modelling (e.g. Gerhard et al. 2001; Paper IV) and gravitational lensing (e.g. Treu & Koopmans 2004; Rusin & Kochanek 2005;

Koopmans et al. 2006) suggests that both assumptions are reasonably well justified in real galaxies.

In Krajnović et al. (2005) and Paper IV, we showed that there is evidence for the inclination to be possibly degenerate, even with the knowledge of the LOSVD at all spatial positions. As discussed in Paper IV, we adopted for our models the assumption-dependent inclination derived by fitting two-integral Jeans models. This inclination appears to provide values in agreement with the geometry of dust/gas discs when they are present. However, for 14 of the 24 modelled galaxies the inclination is already constrained by arguments independent of the dynamics. In fact, nine galaxies (NGC 821, 3156, 3377, 4473, 4550, 5845, 4621, 4660 and 5845) show significantly discy isophotes and require Gaussians flatter than $q' \lesssim 0.4$ in their MGE models (see Paper IV). Under the assumption of axisymmetry, this implies they cannot be too far from edge-on ($i \gtrsim 70^\circ$; see Cappellari 2002, Section 2.2.2). The inclination of five of the remaining galaxies can be derived from the geometry of a gas or dust disc, assuming it is in equilibrium in the equatorial plane of an oblate galaxy (NGC 524, 2974, 4150, 4459, 4526), and it agrees with the dynamically determined inclination (Paper IV).

4 MODELLING RESULTS

4.1 Internal velocity moments

Here, we present the orbital distribution of the 24 early-type galaxies of our modelling subsample (Section 2), derived from our Schwarzschild models, at the inclination determined in Paper IV. The models provide a full description of the DF in terms of a three-dimensional set of weights, which could in principle be transformed into a distribution of stellar mass as a function of the three integrals of motion (E , L_z and a non-classical third integral I_3). In this paper, we will mainly focus on a more concise description of the main characteristics of the internal kinematics which can be obtained by computing the first and the second moments of the velocity distribution. Given the assumed axial symmetry, it is sufficient to study the moments in the galaxy meridional plane (R , z).

The results of this section are based on a sample of galaxies which was selected to be consistent with the axisymmetric assumption. The sample contains both fast-rotating and nearly non-rotating galaxies, but it does not include strongly triaxial ones. This has to be considered when drawing statistical conclusions from the models. The results of this section are important to interpret and test the more general results we will obtain using the $(V/\sigma, \varepsilon)$ diagram in Section 5, for the whole SAURON sample which also includes significantly triaxial galaxies.

A large number of studies, in the past 20 years, have shown that E galaxies display a dichotomy between the most massive galaxies, which tend to rotate slowly, are metal rich, have a flat central luminosity profile and show evidence of triaxiality, and the less massive objects, which rotate faster, are metal poor, have a cuspy luminosity profile, and may all be axisymmetric and contain discs (Davies et al. 1983; Bender 1988; Kormendy & Bender 1996; Faber et al. 1997; Lauer et al. 2005).

In the companion paper (Paper IX), we show that a clean separation of the two classes of early-type galaxies is obtained by introducing a new *quantitative* classification parameter λ_R which is related to the specific angular momentum of galaxies (e.g. Bertola & Capaccioli 1978; Bender & Nieto 1990) and which can be measured

from integral-field stellar kinematics as

$$\lambda_R \equiv \frac{\langle R|V| \rangle}{\langle R\sqrt{V^2 + \sigma^2} \rangle} = \frac{\sum_{n=1}^N F_n R_n |V_n|}{\sum_{n=1}^N F_n R_n \sqrt{V_n^2 + \sigma_n^2}}, \quad (1)$$

where F_n is the flux contained inside the n th Voronoi bin and V_n and σ_n are the corresponding measured mean velocity and velocity dispersion (see Paper IX). The numerical values of λ_R for our sample, measured with $1R_e$, are given in Table 1. In this work, we adopt that classification to define the galaxies in our sample with significant angular momentum per unit mass $\lambda_R > 0.1$, which we call ‘fast rotators’ and the ones with negligible amount of specific angular momentum $\lambda_R < 0.1$, which we define as ‘slow rotators’ (Table 1). Our kinematic classification has a similar spirit to the one proposed by Kormendy & Bender (1996), but contrary to the latter, which was based on the galaxy isophotal shape, our classification is quite robust against projection effects.

In Fig. 1, we plot the internal moments in the meridional plane of our subsample of 24 modelled galaxies. The ellipses represent the cross-section of the velocity ellipsoids at various positions in the galaxy body, while the colours visualize the ratio $\langle v_\phi \rangle / \bar{\sigma}$ between the mean velocity around the symmetry axis and the local mean velocity dispersion $\bar{\sigma}^2 = (\sigma_r^2 + \sigma_\theta^2 + \sigma_\phi^2)/3$, where $\sigma_\phi^2 = \langle v_\phi^2 \rangle - \langle v_\phi \rangle^2$. Here, (r, θ, ϕ) are the standard spherical coordinates (ϕ is the azimuthal angle around the galaxy symmetry axis). The quantity $\langle v_\phi \rangle / \bar{\sigma}$ is a local analogue, inside the galaxy body, of the global quantity V/σ which measures the importance of rotation with respect to the random motions. In the plot, the galaxies were sorted according to the λ_R parameter. The first nine galaxies are classified as slow rotators, while the remaining 15 as fast rotators.

The slow rotators in this modelling subsample are all intrinsically quite round, with an axial ratio of the density $q \gtrsim 0.8$. This result depends on the correctness of the assumed inclination, which in all cases is best fitted as edge-on ($i = 90^\circ$). This inclination cannot be correct in all cases, however these objects are all very round in projection, which statistically implies they are intrinsically not far from spherical. The flattest slow rotator of this subsample has an apparent axial ratio of $q' \approx 0.8$ and assuming it has the mean inclination of a randomly oriented sample ($i = 60^\circ$), it would still have an intrinsic axial ratio $q \approx 0.7$. As we verified numerically with our models, for nearly round models the results for the orbital distribution change little with inclination, as can be understood from the obvious fact that a spherical model appears identical from any inclination. In particular, we constructed models for NGC 3379, 4486 and 4552 at an inclination of $i = 45^\circ$ and found virtually unchanged anisotropy results. The slow rotators of this subsample are generally characterized by a nearly round velocity ellipsoid in the meridional plane and do not show any significant rotation. A clear exception is NGC 4550, which shows internal rotation and a strongly flattened velocity ellipsoid.

Our anisotropy results could be significantly in error if the slow rotators of our modelling subsample were intrinsically flattened and nearly face-on objects ($i \sim 0$). However, the small apparent ellipticity of the slow rotators is also generally true for the whole SAURON sample. That sample includes some flatter and clearly triaxial slow rotators, however the smallest apparent axial ratio of any slow rotator is still $q' \approx 0.7$. Statistically, this implies the ratio of the shortest and longest axis of the intrinsic density is $c/a \gtrsim 0.7$. In Paper IX, we show that the slow rotators are truly different from the fast rotators and do not simply *appear* different due to projection. All this makes it very unlikely that any of the slow rotators we modelled is a flat

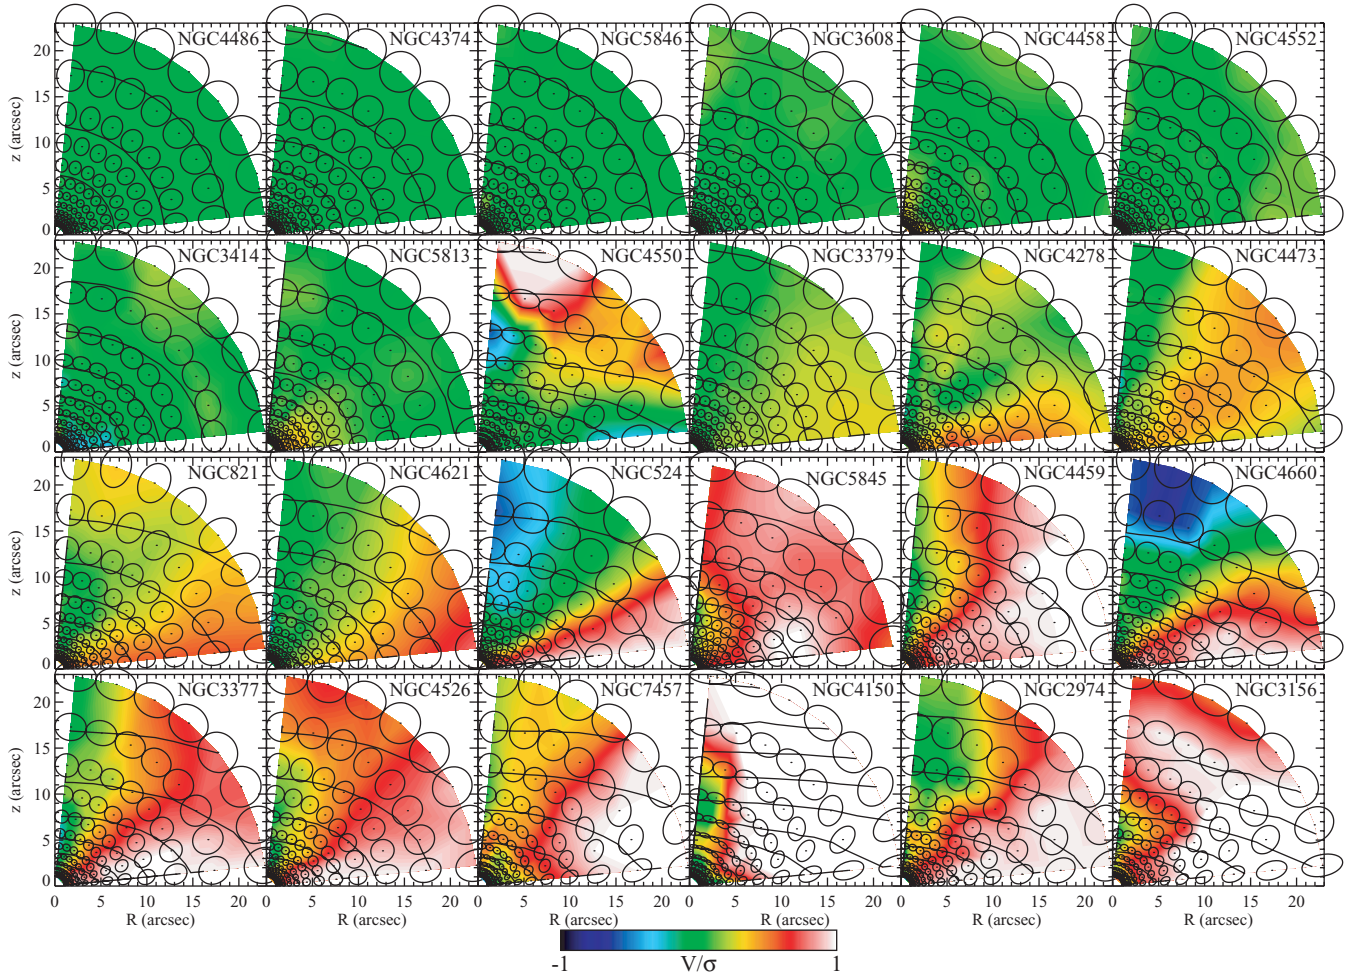

Figure 1. Internal moments of the modelling subsample. The colours visualize the ratio $\langle V \rangle / \bar{\sigma}$ of the first and second internal moment of the velocity, in the positive quadrant of the meridional plane (R, z), for the 24 galaxies of the modelling subsample. The contours of the intrinsic density are overlaid. The ellipses are cross-sections of the velocity ellipsoid with the (v_R, v_z) plane at different locations (one of the principal axes of the ellipsoid is orthogonal to the plane). The objects are sorted, from left- to right-hand side and from top to bottom, according to the parameter λ_{R_e} (Table 1) which is related to the specific angular momentum per unit mass. The first nine galaxies are classified as slow rotators ($\lambda_{R_e} < 0.1$) and the remaining 15 as fast rotators ($\lambda_{R_e} > 0.1$). All panels have the same size, which roughly corresponds to the area fully covered by the observed SAURON kinematics.

system seen nearly face-on and implies our anisotropy results for the subsample are reliable.

The fast rotators appear to span a large range of intrinsic flattening with $q \approx 0.3$ – 0.9 . For the flat objects, the maximum contribution to rotation generally occurs on the galaxy equatorial plane, as expected, but an important exception is NGC 4473, which has a minimum of the velocity contribution on the major axis (as NGC 4550). The orbital structure of the two special cases, NGC 4473 and 4550, will be explained in Section 4.5. The fast rotators are generally significantly anisotropic, with large variations in the ratio σ_r / σ_θ . As a first approximation, the velocity ellipsoid tends to be aligned in polar coordinates and appears to be flattened in the same direction as the density distribution, in the sense that $\sigma_r < \sigma_\theta$ along the galaxy rotation axis, while $\sigma_r > \sigma_\theta$ on the equatorial plane. Using cylindrical coordinates in the meridional plane (R, z), one may broadly describe the observed shape of the velocity ellipsoid as being generally flattened along the z direction. There seems to be a tendency for the anisotropy to be stronger near the equatorial plane, especially in disc-dominated galaxies like NGC 3156, 4150 and 7457.

4.2 Global velocity dispersion tensor

In the previous section, we described the variations of the velocity ellipsoid as a function of position inside the galaxies. In this section, we consider global integrated quantities for each galaxy. A classic way to quantify the global anisotropy in galaxies is by using the anisotropy parameter (Binney & Tremaine 1987, Section 4.3)

$$\delta \equiv 1 - \frac{\Pi_{zz}}{\Pi_{xx}}, \quad (2)$$

where z coincides with the symmetry axis of an axisymmetric galaxy, x is any fixed direction orthogonal to it and

$$\Pi_{kk} = \int \rho \sigma_k^2 d^3 \mathbf{x}, = \sum_{n=1}^N M_n \sigma_{k,n}^2, \quad (3)$$

with σ_k the velocity dispersion along the direction k at a given location inside the galaxy. The summation defines how we computed this quantity from our Schwarzschild models. M_n is the mass contained in each of the N polar bins in the meridional plane of the model, and $\sigma_{k,n}$ is the corresponding mean velocity dispersion along the

direction k . At any location in the galaxy, the velocity ellipsoid is defined by having the principal axes along the directions which diagonalize the tensor σ . We define two additional anisotropy parameters:

$$\beta \equiv 1 - \frac{\Pi_{zz}}{\Pi_{RR}} \quad (4)$$

describes the global shape of the velocity dispersion tensor in the (v_R, v_z) plane. $\beta = 0$ if the intersection of the velocity ellipsoid in the (v_R, v_z) plane (as shown in Fig. 1) is everywhere a circle. This is the case, for example, if the DF depends only on the two classical integrals of motion $f = f(E, L_z)$, where E is the energy and L_z is the angular momentum parallel to the z -axis. If the shape of the velocity ellipsoid is constant inside the galaxy body, then $\beta = 1 - (\sigma_z/\sigma_R)^2$. The second parameter

$$\gamma \equiv 1 - \frac{\Pi_{\phi\phi}}{\Pi_{RR}} \quad (5)$$

describes the global shape of the velocity dispersion tensor in a plane orthogonal to v_z . $\gamma = 0$ when the intersection of the velocity ellipsoid with a plane orthogonal to the v_z axis is a circle everywhere. $\beta = \gamma = \delta = 0$ for an isotropic system (spherical velocity ellipsoid everywhere). Integrating over the azimuthal angle, one finds

$$\Pi_{xx} = \frac{\Pi_{RR} + \Pi_{\phi\phi}}{2}, \quad (6)$$

so that the three anisotropy parameters are related by

$$\delta = \frac{2\beta - \gamma}{2 - \gamma}. \quad (7)$$

In the case $\gamma = 0$, the anisotropy can be measured directly in the meridional plane and the simple relation $\beta = \delta$ applies.

We evaluated these anisotropy parameters from the solution of the Schwarzschild models, restricting the volume integral of equation (3) *only* within the radius ($R < 25$ arcsec) fully constrained by the kinematics which is shown in Fig. 1. The results are shown in the top two panels of Fig. 2. In general, we find that $\delta \sim \beta$ [similar to the non-classic two-integral models of Dehnen & Gerhard (1993)], while there is no obvious trend of γ with increasing anisotropy δ . This means that the observed anisotropy is mainly due to a flattening of the velocity dispersion ellipsoid in the v_z direction. However, most of galaxies have $\gamma \gtrsim 0$, indicating mild radial anisotropy. Just a few galaxies have instead tangential anisotropy ($\gamma \lesssim 0$), and in particular NGC 4473 and 4550 stand out (see Section 4.5).

The near isotropy of the roundest galaxies is not surprising in this plot, in fact the anisotropy parameters are computed in cylindrical coordinates (R, z) , as best suited for oblate bodies. By construction, all the anisotropy parameters are zero by symmetry in the spherical limit. This is a known feature of the $(V/\sigma, \varepsilon)$ diagram as well, where spherical objects necessarily have zero anisotropy δ . To measure the anisotropy of nearly spherical galaxies, one can define a complementary anisotropy parameter, in spherical coordinates:

$$\beta_r \equiv 1 - \frac{\Pi_{tt}}{\Pi_{rr}}, \quad (8)$$

with

$$\Pi_{tt} = \frac{\Pi_{\theta\theta} + \Pi_{\phi\phi}}{2}, \quad (9)$$

and (r, θ, ϕ) the standard spherical coordinates. In the spherical limit, assuming the galaxy is non-rotating, $\Pi_{\theta\theta} = \Pi_{\phi\phi} = \Pi_{rr}$ by symmetry. The parameter is $\beta_r = 0$ for an isotropic galaxy and is positive (negative) when the luminosity-weighted average dispersion along the radial direction is larger (smaller) than the average dispersion

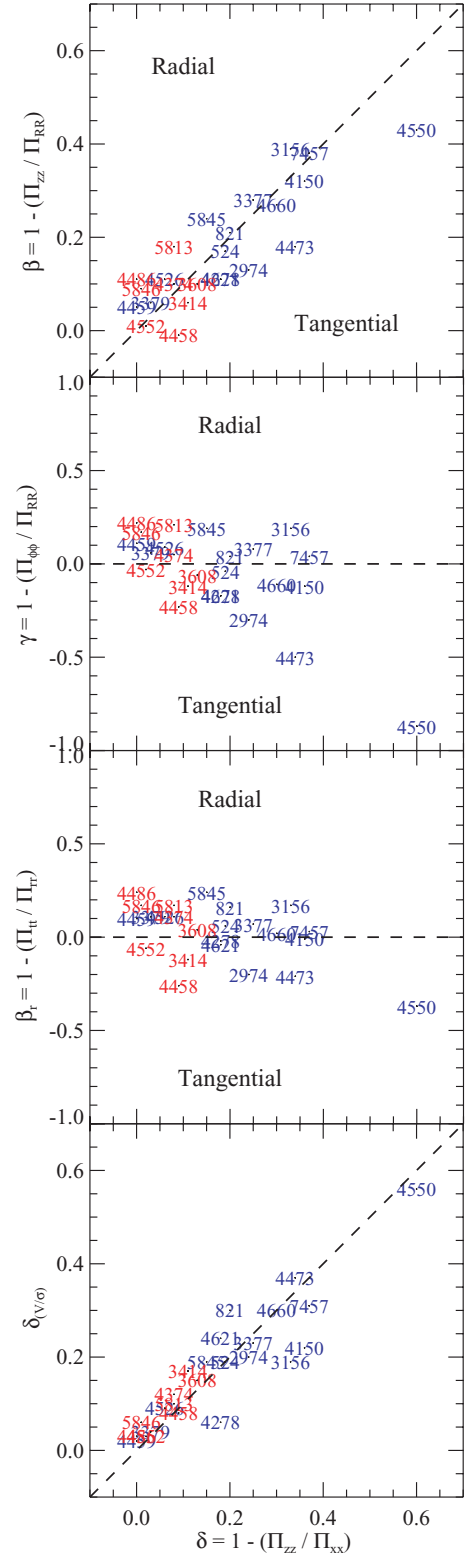

Figure 2. Global anisotropy from the dynamical models. Comparison between the anisotropy δ determined from the 24 Schwarzschild models of Fig. 1 and the anisotropy parameter β (top panel), γ (second panel) and β_r (third panel). Bottom panel: comparison between δ from the models and $\delta_{(V/\sigma)}$ from the $(V/\sigma, \varepsilon)$ diagram of Fig. 3, after correction for the inclination. The red and blue labels refer to the slow and fast rotators, respectively.

along any direction orthogonal to it. The plot of β_r versus δ is shown in the third panel of Fig. 2. It confirms that the small anisotropy of the slow rotators in the top two panels is not an artefact of the adopted coordinate system. This can also be seen qualitatively in Fig. 1, which shows that the intersection of the velocity ellipsoids of the slow rotators with the (v_R, v_z) plane is nearly a circle ($\sigma_\theta \approx \sigma_r$). None of the roundish slow rotators appears to be dominated by radial anisotropy in the regions that we observe and the inferred values of $|\beta_r| \lesssim 0.2$ imply that the average shape of the velocity ellipsoid for the roundish galaxies does not differ by more than ≈ 10 per cent from a spherical shape.

The results in this section quantify what we discussed qualitatively in Section 4.1, namely the fact that the slow rotators in the modelling subsample of 24 galaxies tend to be nearly isotropic, while the fast rotators span a large range of anisotropies. As a consistency test, in Appendix A we use two-integral Jeans models to show that the slow rotators are well reproduced by isotropic models in their central regions, while the flat fast rotators are not. The same considerations on the bias of the selection of this modelling subsample against strongly triaxial galaxies, that we discussed in Section 4.1, also apply to the results of this section.

The anisotropy we measured was derived by fitting kinematical data which have limited spatial coverage, so the values are not necessarily representative of the galaxy as a whole. In Krajnović et al. (2005), we showed that the orbital distribution inferred from our orbital-superposition models, in the case of integral-field data with limited spatial coverage, is accurate in the region of the galaxy for which we have kinematical data, which in our case generally corresponds to $1R_e$. For most of the slow rotators, however, we generally do not reach $1R_e$ with our SAURON data. This has to be kept in mind when comparing our results to the results obtained, for example, from numerical simulations.

4.3 Comparison with previous modelling results

The modelling results discussed in this paper are the first based on integral-field stellar kinematics, which is critical for the recovery of the orbital distribution of flattened galaxies. No previous results are available using a comparable technique. In the spherical limit, however, observations along a single slit position are in principle sufficient to uniquely recover the DF (Dejonghe & Merritt 1992). The anisotropy we derive for the roundest galaxies can be compared with previous results obtained using spherical models.

The largest set of spherical models of galaxies in common with our sample is the one presented in Kronawitter et al. (2000) and analysed in Gerhard et al. (2001). The five galaxies in common with our modelling subsample of 24 galaxies are NGC 3379, 4278, 4374, 4486 and 5846. The galaxy with the largest apparent ellipticity is NGC 4374, which has $\varepsilon = 0.15$, so our models, which take the small non-zero ellipticity into account, do not differ too much from spherical models, and we can compare the results obtained with different kinematical data and different methods. For four of the galaxies, we find that the small radial anisotropy $\beta_r \approx 0.1$ – 0.2 that we measure does not differ by more than $\Delta\beta_r \lesssim 0.1$ from the β_{mean} (kindly provided by O. Gerhard) of Gerhard et al. (2001), which is the unweighted mean of their radial anisotropy within $1R_e$ (their fig. 5). This error corresponds to a difference of just 5 per cent on the mean flattening of the velocity ellipsoid in these galaxies. This value likely represents the realistic systematic error one can expect from this type of measurements with current data and techniques. For one galaxy, NGC 4278, they measure a strong anisotropy $\beta_{\text{mean}} \approx 0.3$, while we derive near isotropy $\beta_r \approx 0$. The difference

could be explained by the fact that the data of Kronawitter et al. (2000) for this galaxy are not very extended in radius $R \lesssim R_e/3$ and possess the lowest quality of the considered test sample.

Another systematic study of the anisotropy of a sample of 12 early-type galaxies, using an axisymmetric Schwarzschild method similar to the one adopted for the present paper, was performed by Gebhardt et al. (2003). We can compare the results for the five galaxies in common that we both modelled as edge-on NGC 821, 3377, 3379, 3608 and 5845. For this, we computed from our models an approximation to their mean ratio $(\sigma_r/\sigma_t)_{R_e/4}$ (their tables 1 and 3). Contrary to our anisotropy parameter β_r , their ratio is *not* directly related to the shape of the velocity ellipsoid, as it includes both random and ordered azimuthal streaming (see their section 4.7). In particular, according to their definition, unless the galaxy is spherical, an isotropic model will have $(\sigma_r/\sigma_t) < 1$, while a ratio of unity indicates radial anisotropy ($\beta_r > 0$). Trying to closely reproduce their measurements on our models, we obtain a ratio $(\sigma_r/\sigma_t)_{R_e/4} \approx 1.0$ for all five galaxies, with maximum differences of 10 per cent between ours and their results. This consistency test is not as useful as the previous one, as it does not allow us to test our derivation of the shape of the velocity ellipsoid in flattened galaxies. However, for the two nearly round objects, NGC 3379 and 3608, both sets of models show that these galaxies are very nearly isotropic.

In summary, the comparison between our anisotropy determinations and those of previous authors, on two limited samples of five models each, indicates a general agreement and suggests that our systematic errors are of the order of 5 per cent on the shape of the velocity ellipsoid.

4.4 Comparison with the $(V/\sigma, \varepsilon)$ diagram

In the previous sections, we studied the anisotropy in galaxies by direct inversion of the observed kinematics and photometry using axisymmetric dynamical models. In this section, we revisit the previous findings with the classic $(V/\sigma, \varepsilon)$ diagram (Binney 1978), as was done for the last 30 years. This will provide a link between our results and the classic ones, and in addition it will allow us to test the robustness of the derived values.

In Fig. 3, we visualize the location of the slow and fast rotator samples in the $(V/\sigma, \varepsilon)$ diagram. Traditionally, the observed V/σ quantity is computed from the central velocity dispersion and the maximum rotational velocity (but see Bacon 1985). Recently, Binney (2005) updated the formalism to compute the quantity in a more robust way, from integral-field data. Here, the availability of SAURON integral-field kinematics allows us to apply this new formalism for the first time to real galaxies. We use the updated formulae and define

$$\left(\frac{V}{\sigma}\right)_e^2 \equiv \frac{\langle V^2 \rangle}{\langle \sigma^2 \rangle} = \frac{\sum_{n=1}^N F_n V_n^2}{\sum_{n=1}^N F_n \sigma_n^2} \quad (10)$$

as a luminosity-weighted quantity, which we estimate from the binned SAURON kinematics. Here, F_n is the flux contained inside the n th Voronoi bin and V_n and σ_n are the corresponding measured mean velocity and velocity dispersion. Similarly, we define the ellipticity as

$$(1 - \varepsilon)^2 = q^2 = \frac{\langle y^2 \rangle}{\langle x^2 \rangle} = \frac{\sum_{n=1}^N F_n y_n^2}{\sum_{n=1}^N F_n x_n^2}, \quad (11)$$

where the (x, y) coordinates are centred on the galaxy nucleus and the x -axis is aligned with the galaxy photometric major axis. We estimate ε from the individual SAURON pixels, inside a given galaxy

Figure 3. $(V/\sigma, \varepsilon)$ diagram for our modelling subsample of 24 galaxies. The red and blue labels refer to the NGC number of the slow and fast rotators, respectively, and show the measured values of the luminosity-weighted ellipticity ε and V/σ . The solid lines, starting from each object, show the effect of correcting the observed values of each galaxy to an edge-on view (diamonds). For the fast rotators, we adopted the inclination derived from the models of Paper IV. For the slow rotators, we show the correction for inclination assuming the average inclination of a randomly oriented sample $i = 60^\circ$. Even under this assumption, the corrections are small for the slow rotators. The grid of solid curves shows the location on this diagram of edge-on oblate galaxies with different anisotropy $\delta = 0, 0.1, \dots, 0.6$ (edge-on isotropic models $\delta = 0$ are shown with the thick green line).

isophote, within the same region used for the computation of V/σ . This way of measuring ε by diagonalizing the inertia tensor of the galaxy surface brightness is the standard technique among N -body modellers (e.g. Carter & Metcalfe 1980) and for the automatic determination of ε in large galaxy surveys (e.g. Bertin & Arnouts 1996). When the ellipticity varies little with radius, the ε measured with this technique is very similar to the intensity-weighted ε (Ryden et al. 1999) from the standard photometry profiles (see also Fig. 14). In general, however, the ε determinations from the moments are biased towards larger radii than ε determinations from the profiles.

For a rigorous application of the $(V/\sigma, \varepsilon)$ diagram, the summation (10) should extend to infinite radii and the ε should be constant with radius. In Appendix B, we show that reliable results for the $(V/\sigma, \varepsilon)$ values (at least in the limited isotropic case considered) can still be obtained when the summation is spatially limited and the ellipticity is slowly varying. To make the measurement comparable between different galaxies, we limit the summation to $1R_e$, or to the largest observed radius, whichever is smaller. We also show that better results are obtained when the summation is performed inside ellipses instead of circles. For this reason, the quoted values of V/σ are measured inside ellipses of area $A = \pi R_e^2$ and semimajor axis $a = R_e/\sqrt{1-\varepsilon}$, where the mean ellipticity ε is measured inside an isophote of the same area A . When the isophote/ellipse are not fully contained within the observed SAURON field of view, we limit the summation to the largest isophote/ellipse contained within the field. The $(V/\sigma, \varepsilon)$ values are given in Table 1.

The $(V/\sigma, \varepsilon)$ diagram for the 24 galaxies of the modelling subsample is shown in Fig. 3. The solid curves in the $(V/\sigma, \varepsilon)$ diagram represent the location of oblate edge-on models with different anisotropy δ . Real galaxies are generally not seen edge-on, so a correction for the effect of inclination is in principle needed to correctly interpret the diagram. This usually cannot be done, as the inclination of early-type galaxies is not easy to determine. In our case, however, we have an estimate for the inclination of our galaxies (Section 3), so we can correct the position of our objects on the diagram to the edge-on case. Although the inclination we use is assumption dependent, we showed in Paper IV that it generally provides a big improvement from a complete lack of knowledge of the inclination.

For a galaxy observed at an inclination i (edge-on corresponding to $i = 90^\circ$), with an ellipticity ε and a given ratio $(V/\sigma)_{\text{obs}}$, the values corrected to an edge-on view are (Binney & Tremaine 1987, Section 4.3)

$$\left(\frac{V}{\sigma}\right)_e = \left(\frac{V}{\sigma}\right)_{\text{obs}} \frac{\sqrt{1-\delta\cos^2 i}}{\sin i}, \quad (12)$$

$$\varepsilon_{\text{intr}} = 1 - \sqrt{1 + \varepsilon(\varepsilon - 2)/\sin^2 i}. \quad (13)$$

Starting from a given set of edge-on parameters, the anisotropy under the oblate assumption is obtained as (Binney 2005)

$$\delta = 1 - \frac{1 + (V/\sigma)^2}{[1 - \alpha(V/\sigma)^2] \Omega(e)} \quad (14)$$

where

$$e = \sqrt{1 - (1 - \varepsilon_{\text{intr}})^2}, \quad (15)$$

$$\Omega(e) = \frac{0.5(\arcsin e - e\sqrt{1-e^2})}{e\sqrt{1-e^2} - (1-e^2)\arcsin e} \quad (16)$$

and α is a dimensionless number, which does not depend on the galaxy amount of rotation, but only on how the stellar density ρ and streaming velocity v_ϕ are distributed in the (R, z) plane. In Appendix B, we use Jeans models to show that a value $\alpha \approx 0.15$ places isotropic models, with a realistic surface brightness distribution, close to the isotropic line on the $(V/\sigma, \varepsilon)$ diagram. Although α may in principle vary for different galaxies, tests suggest variations to be small and we will use this value for all the $(V/\sigma, \varepsilon)$ diagrams in this paper. As the inclination correction requires the knowledge of both the known inclination i and the unknown anisotropy δ , one has to proceed in an iterative manner. However, this process converges very rapidly, as the correction depends very little on δ . The effect of correcting the observed values of our galaxies on the $(V/\sigma, \varepsilon)$ diagram is shown in Fig. 3.

The comparison between the anisotropy derived from the inclination-corrected $(V/\sigma, \varepsilon)$ diagram and from the dynamical models is shown in the bottom panel of Fig. 2. The generally good agreement confirms the reliability of the two approaches and the significant anisotropy of most of the fast rotators in the modelling subsample.

As pointed out by Kormendy (1982a), in the formalism of Binney (1978) the isotropic line in the $(V/\sigma, \varepsilon)$ diagram is approximated to good accuracy by the expression $(V/\sigma)^2 \approx \varepsilon/(1-\varepsilon)$. Similarly, in the revised formalism for integral-field kinematics of Binney (2005), which we adopt in this paper, the minimax rational approximation of order (1,1) to the isotropy line (equation 14 with $\delta = 0$ and $\alpha = 0$) is given by

$$\left(\frac{V}{\sigma}\right)_e \approx 0.890 \sqrt{\frac{\varepsilon}{1-\varepsilon}}, \quad (17)$$

which has a maximum relative error of just 0.3 per cent over the whole interval $\varepsilon = [0.01, 0.99]$. For the adopted value of $\alpha = 0.15$ (Appendix B), the corresponding approximation to the isotropic line becomes

$$\left(\frac{V}{\sigma}\right)_e \approx 0.831 \sqrt{\frac{\varepsilon}{1 - 0.896 \varepsilon}}, \quad (18)$$

which has a maximum fractional error of just 0.2 per cent in the same interval.

4.5 Understanding the anisotropy

We saw in Section 4.2 that the anisotropy of early-type galaxies tends to be due to a flattening of the velocity ellipsoid along the z direction, parallel to the symmetry axis. However, two galaxies, NGC 4473 and 4550, stand out for being dominated by tangential dispersion. Understanding what makes some objects special is key to understand the normal galaxies.

In Fig. 4, we show the data versus model comparison for the galaxy NGC 4550, while the same comparison for NGC 4473 was shown in fig. 2 of Cappellari & McDermid (2005). Along the major axis both galaxies show a peculiar decrease in the V field and a corresponding increase in the σ field. As already pointed out by Rubin, Graham & Kenney (1992) and Rix et al. (1992), for the case of NGC 4550, a natural explanation for this behaviour is the presence of two counter-rotating stellar components, as indicated by the observed double-peaked line profiles. In Fig. 5, this explanation is confirmed

from the solution of the Schwarzschild models, which shows two major kinematically distinct stellar components, rotating in opposite directions. In all the fits, we adopted a modest regularization [$\Delta = 10$; see van der Marel et al. (1998) for a definition]. In addition, the SAURON data allow us to find that the two discs have very different scaleheights. Integrating the solution over the whole model, we find that in NGC 4450 the counter-rotating component constitutes about 50 per cent of the total mass, while in the case of NGC 4473 the counter-rotating component is about 30 per cent of the total mass. A more detailed analysis of the incidence of kinematically distinct components in early-type galaxies goes beyond the scope of the present paper.

For comparison with the two peculiar cases, in Fig. 4 we also show the best-fitting model for the prototypical fast-rotating discy E NGC 4660 (Bender, Saglia & Gerhard 1994) and the corresponding model solution in Fig. 5. We also show the model solution for the prototypical slow-rotating giant E NGC 4486 (M87; the best-fitting model was shown in fig. 3 of Cappellari & McDermid 2005). It appears that the fast rotators tend to be characterized by flat stellar components (orbital starting conditions close to the equatorial plane) with angular momentum significantly smaller than the circular orbit (starting conditions far from the bottom left/right corners of the plot). The relatively low angular momentum of these flat components produces a significant radial dispersion, which is the main reason of the observed anisotropy. The dominant radial dispersion in these flat disc-like stellar components is reminiscent of the one observed in disc galaxies, and generally attributed to disc heating

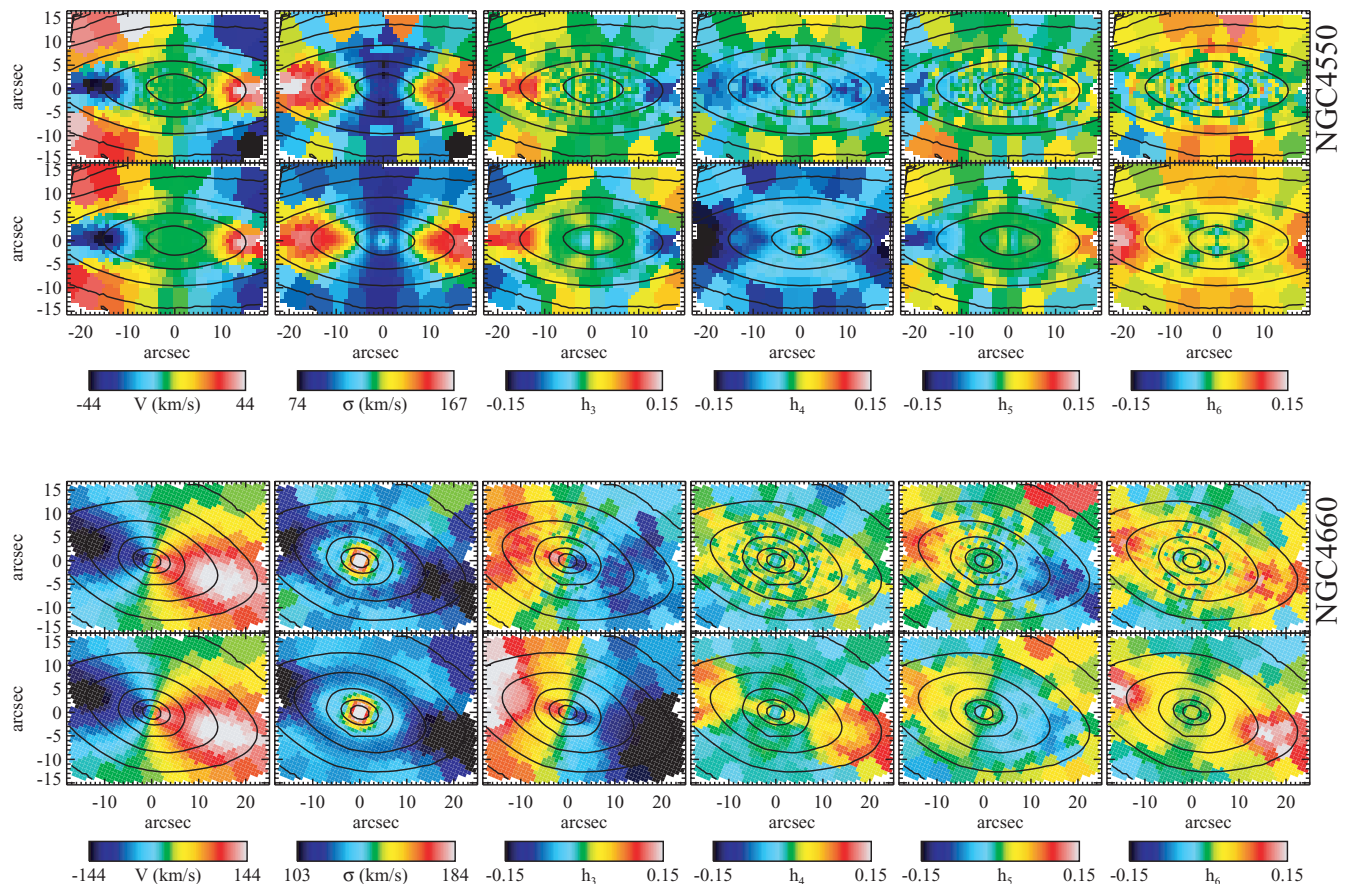

Figure 4. Data–model comparison. Each column from left- to right-hand side shows the kinematical moments: mean velocity, V , velocity dispersion, σ , and higher Gauss–Hermite moments, h_3 – h_6 . Top row: Voronoi binned (Cappellari & Copin 2003) and bi-symmetrized SAURON observations. Bottom row: three-integral Schwarzschild best-fitting model. The two fits correspond to NGC 4550 (top) and NGC 4660 (bottom), respectively.

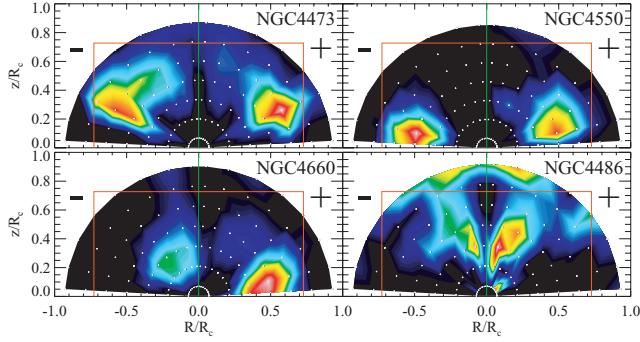

Figure 5. Integral space at a given energy for the solution of the Schwarzschild models for the galaxies NGC 4473, 4550, 4660 and 4486. Each panel plots the meridional plane (R, z) with the location (white dots) where orbits are started with $v_R = v_z = 0$ at the given energy. For nearly edge-on galaxies, the white dots also correspond to the position of the orbital cusps, where every orbit gives its strongest contribution to the observables on the sky plane. The energy was chosen as that of a circular orbit with radius $R_c = 32$ arcsec, which is about the size of the observed SAURON field (red rectangle). The coloured contours show the fraction of mass assigned to different orbits at that energy, where bright colours correspond to high-mass fractions. Orbits at negative and positive R starting conditions correspond to prograde and retrograde, respectively. Orbits with high angular momentum are found in the bottom right and bottom left corner, respectively, on the plots. Orbits near the symmetry axis (green line) have low angular momentum. Orbits near the equatorial plane ($z = 0$) are intrinsically flat (see fig. 6 of Paper IV for a detailed explanation of this diagram).

processes (e.g. Shapiro, Gerssen & van der Marel 2003). In some cases, the disc-like components may happen to counter-rotate, or two discs may be present, in which case tangential anisotropy dominates the observed anisotropy.

Interestingly, the disc-like components, which tend to characterize the fast rotators, not only seem to be distinct in integral space, but also differ in terms of their stellar population. As shown in fig. 11 of Kuntschner et al. (2006, hereafter Paper VI), all the flat fast rotators are characterized by an Mgb line-strength distribution which is flatter than the isophotes. The fact that a flat Mgb is seen in all the flat galaxies suggests that perhaps *all* the fast rotators contain this metallicity-enhanced disc-like component, which is only visible in the flattest objects because they are closer to edge on. This result is reminiscent of the finding by Lauer et al. (2005) that all flat cuspy galaxies show a disc. This metallicity enhancement indicates that additional star formation activity happened in the disc and, not surprisingly, implies that gas dissipation was involved in the formation of these flat structures. The radial anisotropy, however, shows that heating was significant after the disc formation, as otherwise the stars in the flat components would still move on orbits that are closer to circular.

4.6 Relation of anisotropy with other global observables

In Fig. 6, we show the correlation between the anisotropy and the galaxy velocity dispersion σ_e within the effective radius, taken from Paper IV. There is a trend for the most massive galaxies to have a *smaller* anisotropy within one R_e , with the exception of the special case NGC 4458 (see also Paper IV, Section 5.1). In this diagram, we use the parameter β to characterize the anisotropy. This parameter is measured in the galaxy meridional plane so it describes the orbital distribution in a way that is not affected by the direction of rotation of the stars in the galaxy. The β parameter measures the same

Figure 6. Anisotropy parameter β in the meridional plane versus the luminosity-weighted second moment σ_e of the stellar velocity (from Paper IV). The red and blue labels refer to the slow and fast rotators, respectively.

Figure 7. Anisotropy parameter β in the meridional plane versus the average *intrinsic* ellipticity ϵ_{intr} of the galaxies. The observed anisotropy is related to the intrinsic ellipticity of the galaxies. The thick black solid line is the best-fitting relation. The dashed lines show the predictions of the tensor virial equations, in the form of equation (14), for different values of the $V/\sigma = 0, 0.25, \dots, 1$ (see text for details). The red and blue labels refer to the slow and fast rotators, respectively. The magenta line shows the same relation $\beta = 0.7\epsilon_{\text{intr}}$ as the one in Fig. 9, while the green line indicates isotropy.

anisotropy, for example, in two galaxies that formed with the same physical process, but in which one galaxy experienced a merger in a prograde direction and the other in a retrograde direction.

A general trend is found between anisotropy and the intrinsic galaxy ellipticity (Fig. 7). The best-fitting relation to this rather scattered distribution of points, using a robust bisector algorithm, has the form

$$\beta = (0.6 \pm 0.1) \epsilon_{\text{intr}}. \quad (19)$$

Given that the errors on both β and ϵ_{intr} are model dependent and difficult to estimate, we adopted constant errors on both variables. The quoted error on the slope was determined by enforcing the condition $\chi^2 = \nu$, where ν is the number of degrees of freedom of the fit.

A better understanding of the meaning of the observed trend comes by considering the region in the $(\beta, \varepsilon_{\text{intr}})$ plane that is allowed by the tensor virial equations. Equation (14) defines in fact a relation between the three variables $\varepsilon_{\text{intr}}$, V/σ and δ . This equation is usually visualized in the observational plane $(V/\sigma, \varepsilon_{\text{intr}})$ for different values of δ as in Fig. 3. The same equation can be plotted in the theoretical plane $(\delta, \varepsilon_{\text{intr}})$ for different values of V/σ . As we saw that in real galaxies we have in general $\beta \sim \delta$ (Fig. 2), we will use the relation to understand the location of galaxies in the $(\beta, \varepsilon_{\text{intr}})$ plane (Fig. 7). As expected, within the numerical approximations and the limited spatial coverage, the galaxies generally lie within the region allowed by the tensor virial equations. The observed trend implies a specific form of the increase of the V/σ with increasing $\varepsilon_{\text{intr}}$.

A possible caveat is that a trend of the *average* anisotropy with increasing $\varepsilon_{\text{intr}}$ should be expected even if the galaxies were uniformly distributed in β at every $\varepsilon_{\text{intr}}$, due to the limits on β imposed by the virial equilibrium. However, the 24 galaxies in the modelling subsample do not appear uniformly distributed in β . Moreover, we show in the Appendix C that a uniform distribution in β is not able to reproduce the observed distribution of all the galaxies of the SAURON sample on the $(V/\sigma, \varepsilon)$ diagram: a general trend, and an upper limit of anisotropy as a function of ellipticity, is required to explain the data. As this trend is not implied by the tensor virial equations alone (nothing prevents all galaxies to scatter around $\beta \sim 0$), the observed distribution must hold a fossil record of the process that led to the galaxy formation.

One explanation of the correlation may be that flatter galaxies were more strongly affected by dissipation before star formation was completed. Dissipation naturally makes a galaxy flat by reducing the kinetic energy in the direction parallel to the global angular momentum. Dissipation is also required to produce the small observed kinematical misalignments for the fast rotators of the whole sample (Fig. 8).

Figure 8. Kinematical misalignment Ψ between the global photometric PA and the mean kinematic PA on the SAURON field. The red diamonds and the blue circles refer to the slow and fast rotators, respectively. Some galaxies are also labelled with their NGC number. The dashed line corresponds to $\Psi = 0$ and the dash-dotted one to $\Psi = 5^\circ$. We find that (i) all galaxies flatter than $\varepsilon \sim 0.2$ have $\Psi \sim 0$, and (ii) all the fast rotators have $\Psi \sim 0$, for any ε (exception is the recent merger galaxy NGC 474). Assuming the SAURON survey constitutes a representative sample, this implies that triaxial galaxies have $(c/a) \gtrsim 0.8$. Strongly prolate galaxies are also excluded from this sample.

5 $(V/\sigma, \varepsilon)$ DIAGRAM OF THE SAURON SAMPLE

In Section 4, we used dynamical modelling to recover the anisotropy of a sample of 24 galaxies extracted from the SAURON representative sample. The galaxies in our sample were separated into two groups of fast and slow rotators (Paper IX). The slow rotators all appear to have small anisotropy, while the anisotropy of the fast rotators seems to be related to the intrinsic ellipticity of each galaxy. One limitation of the analysis is due to the fact that the sample for which dynamical models were constructed is not necessarily representative of the whole galaxy population. To address this problem, we show here that the findings of Section 4 can be extended to the whole SAURON sample of 48 E/S0 galaxies. The results still hold even when we include in the analysis 18 additional E/S0 galaxies that are not part of the survey, but for which SAURON data also exist.

5.1 Intrinsic shape distribution

A first point to address, to be able to simulate the observed distribution of galaxies in the $(V/\sigma, \varepsilon)$ diagram, is to understand what is the shape distribution of the galaxies in the SAURON sample. This is in principle a very difficult and intrinsically degenerate task, as even the full knowledge of the observed distribution of galaxy shapes and of their projected kinematical misalignments is not sufficient to recover the corresponding intrinsic quantities, unless strong assumptions are made (Franx, Illingworth & de Zeeuw 1991). However, the availability of integral-field stellar kinematics allows us to realize that the situation is simpler for real galaxies and that strong conclusions can be reached without any statistical analysis.

In Fig. 8, we plot the kinematical misalignment Ψ for the whole sample of 48 E/S0 galaxies. Ψ is defined as the angle between the projected minor axis of the surface brightness and the direction of the projected kinematical rotation axis, which corresponds to the projected direction of the intrinsic angular momentum (Franx et al. 1991):

$$\sin \Psi = |\sin(\text{PA}_{\text{kin}} - \text{PA}_{\text{phot}})| \quad 0^\circ \leq \Psi \leq 90^\circ. \quad (20)$$

The PA_{kin} is defined as the PA at which the observed SAURON velocity field is best approximated by a bi-antisymmetric version of it and was measured as described in appendix C of Krajnović et al. (2006).

The position angle (PA) of the photometric major axis is obtained using the moments of the surface brightness (Carter & Metcalfe 1980) from the large-scale MDM photometry (Falcon-Barroso et al., in preparation). It generally agrees well with the global PA quoted by catalogues like RC3 and the Two-Micron All-Sky Survey (2MASS) Extended Source Catalogue (Jarrett et al. 2000) when available. It is important to consider a global large-scale PA because (i) early-type galaxies tend to be rounder in their central regions than in the outer parts (Ryden, Forbes & Terlevich 2001). Thus, the photometric axes are generally more accurately determined at large radii. (ii) The central regions can be easily affected by bar perturbations. In the case of a disc galaxy with a bar, we are not interested in the PA of the bar, but we want to measure the PA of the main disc, which is better measured at large radii (e.g. Erwin et al. 2003). In most cases, however, a constant-PA surface brightness distribution describes well the whole galaxy and no distinction needs to be made.

It turns out that nearly all the fast rotators in Fig. 8 have a misalignment $\Psi \sim 0^\circ$ within the measurement errors. In the few cases where the misalignment reaches $\Psi \lesssim 5^\circ$ (e.g. NGC 3377, 3384, 4382, 7332), the non-zero value can be ascribed to the presence

of a bar. The only exception is the galaxy NGC 474 for which $\Psi \approx 40^\circ$. This galaxy appears distorted by a recent merger, as evidenced by prominent stellar shells at large radii (Turnbull, Bridges & Carter 1999). Interestingly, also for the obvious nearly face-on bars NGC 4477 and 4262, characterized by the typical oval shape of the isophotes (see Paper III), the kinematical PA appears not affected by the bar and is still well aligned with the outer disc, which defines the photometric PA.

In a stationary triaxial system, kinematical misalignments are common due to two reasons: (i) the intrinsic angular momentum can lie anywhere in the plane containing the long and short axis, so the kinematical axes are not necessarily aligned with the principal axes of the density; and (ii) projection effects can produce observed misalignments even when the angular momentum is aligned with a principal axis. The fact that $\Psi \sim 0$ for all the fast rotators can then only be interpreted as strong evidence that these systems are nearly oblate systems. In some cases, the fast rotators contain bars, which provide further evidence for their disc-like nature.

The situation is completely different for the slow rotators. All these objects appear quite round in projection, the flattest one having $\varepsilon \lesssim 0.3$ (excluding the special case NGC 4550). Some of these galaxies show significant kinematical misalignments, although in general the rotation is confined only to the central region, so it is not representative of the whole galaxy. But some galaxies like NGC 5198 can only be genuine triaxial systems (see Paper III). However, the maximum observed ellipticity sets a limit of $c/a \gtrsim 0.7$ on the ratio between the shortest and longest axis of the density. A complete larger sample of slow-rotating galaxies or detailed triaxial dynamical modelling would be needed to investigate the shape distribution of these objects in more detail. The observed difference in shape between the fast-rotating galaxies and the generally brighter slow-rotating ones is consistent with the bimodality in the shape distribution between the fainter and brighter galaxies observed by Tremblay & Merritt (1996). The availability of the stellar kinematics, however, shows that the shape distribution, not surprisingly, is more closely related to the kinematics than to the luminosity alone.

5.2 Projection effects on the $(V/\sigma, \varepsilon)$ diagram

We established in Paper IX and further verified in Section 5.1 that the whole SAURON sample of E/S0 galaxies can be broadly subdivided into a class of fast-rotating and nearly oblate systems and another class of weakly triaxial slowly rotating galaxies. In Section 4.6, we saw that the anisotropy β , measured in the meridional plane of the 24 galaxies in the modelling subsample, is roughly described by the relation $\beta \sim 0.6 \varepsilon_{\text{intr}}$. Moreover, in Section 4.2 we found that with a few notable exceptions $\beta \sim \delta$, where δ is the anisotropy as can be inferred from the $(V/\sigma, \varepsilon)$ diagram. This implies that in most cases, one should also have $\delta \sim 0.6 \varepsilon_{\text{intr}}$. If these relations that we found for a small sample are valid in general, we should be able to model in a statistical way the distribution of the whole sample of fast rotators in the $(V/\sigma, \varepsilon)$ diagram, as a random sample of oblate galaxies, with anisotropy defined by their intrinsic ellipticity $\varepsilon_{\text{intr}}$. The slow rotators should be inconsistent with this distribution, as they are not expected to be well described by oblate systems. A rigorous test of this idea is not possible due to the complex nature of our sample-selection effects (Section 6.2); however an attempt is still made in Appendix C via Monte Carlo simulation. There we show that the observed distribution of galaxies on the $(V/\sigma, \varepsilon)$ diagram is indeed consistent with a nearly linear trend of anisotropy with ellipticity.

Here, we just try to obtain a qualitative understanding of the effect of the inclination on the $(V/\sigma, \varepsilon)$ diagram. For this, we plot in

Figure 9. $(V/\sigma, \varepsilon)$ diagram for the 48 galaxies in the SAURON representative sample. The red diamonds and the blue circles refer to the slow and fast rotators, respectively (Table 1). The magenta line corresponds to the relation $\delta = 0.7 \varepsilon_{\text{intr}}$ for edge-on galaxies. The dotted lines show the location of galaxies, originally on the magenta line, when the inclination is varied. Different lines are separated by steps of 10° in the inclination. The dashed lines are equally spaced in the intrinsic ellipticity.

Fig. 9 with a magenta line¹ a linear relation² $\delta = 0.7 \varepsilon_{\text{intr}}$ for edge-on galaxies. This relation approximately traces the lower envelope described by the location of the observed fast-rotating galaxies on the $(V/\sigma, \varepsilon)$ diagram. It is steeper than the formally best-fitting relation (19), but still within the large errors. It is useful to have a qualitative understanding of the projection effects, as the paths followed by galaxies of different intrinsic $(\delta, \varepsilon_{\text{intr}})$ are nearly parallel, when the inclination is varied (e.g. Fig. 3). For a given intrinsic ellipticity $\varepsilon_{\text{intr}}$ and anisotropy δ , the corresponding V/σ value, for an edge-on view, is computed with the inverse of equation (14). The dotted lines in Fig. 9 show the location of the galaxies, originally edge-on on the magenta line, when the inclination i is decreased. The projected V/σ and ellipticity values at every inclination are computed with the inverse of equations (12) and (13).

It appears that indeed all the fast rotators lie on the $(V/\sigma, \varepsilon)$ diagram to the left of the magenta line of the edge-on galaxies, as expected if they were a family of oblate models following a general

¹ A compact rational approximation of the magenta line which appears in the $(V/\sigma, \varepsilon)$ diagram of Fig. 9 is given by

$$\left(\frac{V}{\sigma}\right)_e \approx \sqrt{\frac{(0.09 + 0.1\varepsilon)\varepsilon}{1 - \varepsilon}}, \quad (21)$$

which has a 1 per cent accuracy in the useful interval $\varepsilon = [0.01, 0.7]$.

² Any relation between anisotropy and ellipticity for oblate galaxies has to satisfy the necessary condition $(V/\sigma)^2 \geq 0$ in equation (14), or by the Taylor expansion

$$\delta \leq 1 - 1/\Omega(\varepsilon) \approx 0.8\varepsilon + 0.15\varepsilon^2 + 0.04\varepsilon^3 + \dots \quad (22)$$

This implies that the steepest linear relation is $\delta = 0.8\varepsilon$, independently of α . The magenta line is less steep than this limit.

trend of increasing δ for larger ε . The upper envelope of the region spanned by the lines of different inclinations is also generally consistent with the location of the observed galaxies, with reasonable values of the maximum intrinsic ellipticity and anisotropy. The fast rotators for which the inclination was determined independently, with dynamical models or from the dust geometry, generally lie near the expected inclination on the $(V/\sigma, \varepsilon)$ diagram, according to the grid of Fig. 9. The slow rotators on the other hand do not lie in the region allowed by oblate models following the given δ - ε relation. They may not follow any such relation or, more likely, they may not be oblate. This is consistent with the result of Section 5.1 that the fast- and slow-rotating galaxies cannot be described by a single shape distribution. In Appendix C, we also discover that a sharp truncation below the magenta line seems required to explain the observations. This zone of avoidance in the $(V/\sigma, \varepsilon)$ diagram may be related to the stability of axisymmetric bodies with high ellipticity and large anisotropy, and needs to be confirmed with a larger and unbiased sample of galaxies.

Remarkably, only two galaxies fall significantly below the magenta line for $\varepsilon \gtrsim 0.3$. These are the fast-rotator NGC 4473 (marginally) and the special slow-rotator NGC 4550. This was expected from the fact that these two galaxies are dominated by tangential anisotropy (Fig. 2), due to the presence of two counter-rotating discs (Fig. 5). Although they follow the β - ε relation, they do not satisfy the δ - ε relation as they have $\beta < \delta$.

Other significant exceptions are NGC 3156 and 2685, which lie well above the general envelope described by the other galaxies, apparently next to the oblate isotropic line. Do these galaxies actually rotate as fast as an isotropic rotator? They are almost completely disc dominated, as evidenced by the nearly constant velocity dispersion maps, without clear signature of a hot central stellar component (Paper III). If this is the case, they must be intrinsically quite flat and rotate significantly less than an isotropic rotator. For NGC 3156, the inclination $i \approx 68^\circ$ determined via modelling in Paper IV agrees with the inclination inferred from the shape of the outer isophotes, under the assumption of a thin disc geometry. At that inclination, the models show that the galaxy indeed follows the general trend of anisotropy observed for the other galaxies (Fig. 7). A similar discussion is likely to apply to NGC 2685. These two galaxies appear to be special cases of flat and disc-dominated galaxies which are poorly represented in our sample of early-type galaxies.

The observed anisotropy of the fast rotators is consistent with the finding by Burkert & Naab (2005) who recently pointed out that the observed distribution of discy ellipticals on the $(V/\sigma, \varepsilon)$ diagram does not imply isotropy, but can be explained by projection effects on a family of anisotropic and nearly oblate merger remnants, as they obtained as a result of N -body simulations.

5.3 E and S0 galaxies on the $(V/\sigma, \varepsilon)$ diagram

In Paper IX, we showed that early-type galaxies can be subdivided into two homogeneous classes of slow and fast rotators, respectively. The first class is composed almost exclusively of E galaxies, while the second class is composed of both E and S0 galaxies. Now S0 galaxies are defined by the presence of a disc component and it is natural to ask whether all the fast rotators contain a disc, which is not always visible photometrically due to projection effects (Rix & White 1990). In fact, the disc becomes more difficult to detect when the galaxy is away from edge-on. To try to answer this question, we can analyse the galaxies that, according to our simple explanation of Section 5.2, are supposed to be close to edge-on. If they are indeed

edge-on and if they all contain a disc component, this should be visible in the photometry. A detailed analysis of the photometric data will appear in a future paper in this series (Falcon-Barroso et al., in preparation) but we present here a qualitative discussion in relation to the $(V/\sigma, \varepsilon)$ diagram.

We find a range of properties in galaxies near the edge-on magenta line in Fig. 9. At the lowest $V/\sigma \sim 0.1$, there is the S0 galaxy NGC 4382, which shows evidence of interaction, stellar shells and distorted photometry at large radii from our MDM photometry. At higher $V/\sigma \sim 0.2$, we have NGC 821, 4473 and 4621, which are classified as E (Table 1), but show strongly discy isophotes and would be classified as discy ellipticals E(d) according to Kormendy & Bender (1996). An exception is NGC 2768, which does not have evidence for a disc. At higher $V/\sigma \gtrsim 0.3$, we find only S0 galaxies. NGC 4270 has a peanut-shaped bulge, indicative of a nearly edge-on bar, NGC 3377 has strongly discy isophotes, while NGC 4570 and 5308 have a clear thin disc component.

Although the current galaxy sample is too small to reach firm conclusions, we speculate that the observed trend in galaxy properties along the edge-on magenta line can be generalized to understand the whole distribution of the fast rotators on the V/σ diagram. The magenta line seems to describe a sequence of decreasing bulge over total-light ratio B/T . The region of low V/σ is populated by galaxies with $B/T \sim 1$. At increasing V/σ the edge-on magenta line is dominated by S0 galaxies, with $B/T \sim 0.5$ – 0.6 (Simien & de Vaucouleurs 1986). When inclination effects are included on the magenta line, one should expect the upper part of the envelope of the fast rotators to be still dominated by S0 galaxies, where the disc can still be detected even for a non-edge-on view, while the lower part will be populated by non-discy E, where no evidence of the faint disc can be detected unless the galaxies are edge-on. This is what one can qualitatively infer from Fig. 10 where we show the same sample as in Fig. 9, but with the morphological classification included. The decrease of B/T along the magenta line may also be

Figure 10. Galaxy morphology on the $(V/\sigma, \varepsilon)$ diagram. Same as Fig. 9 but here filled triangles represent S0 galaxies and open squares represent Es. The envelope of the fast rotators is populated mainly by S0 in the upper part and by E in the lower part. This is even clearer when the 18 ‘specials’ are included.

the reason for the finding of Paper IX (their fig. 7) that the fast rotators with the largest λ_{R_e} (and thus generally the largest V/σ) tend to be the least massive.

The fact that the fast rotators contain discs constitutes a problem for the characterization of their properties using the $(V/\sigma, \varepsilon)$ diagram. The diagram, in fact, is rigorously valid only for galaxies with a density stratified on similar oblate ellipsoids. This condition is clearly not satisfied for galaxies containing a rounder bulge and a flatter disc component. It would be interesting to understand in detail the orbital distribution of the different photometric components in early-type galaxies, as this constitutes a powerful record of the formation history. This would also be in principle feasible with the integral-field data and Schwarzschild models we have on a few carefully chosen galaxies, as the models do not make any assumption about the galaxy being made by a single stellar component (see e.g. Fig. 5). This goes beyond the scope of the present paper. Here, we note that, from the dynamical models, there seems to be a tendency for the anisotropy to be stronger near the equatorial plane of the few disc-dominated galaxies (Section 4.1). If this is true for the fast rotators in general, one may speculate that the relation between anisotropy and ellipticity is related to the increase of both quantities with increasing B/T . However, the anisotropy is in general not confined to the discs alone, indicating the situation is more complex.

In this paper, we do not attempt a disc-bulge decomposition as we focus on the statistical analysis of a large sample. We only consider the global properties of the stellar orbital distribution in the (possibly heterogeneous) region of the E and S0 galaxies enclosed inside $\sim 1R_e$. Our goal is to study the ordered nature of early-type galaxies as seen on the $(V/\sigma, \varepsilon)$ diagram, in much the same way as a similar set of simple measurements of integrated properties of a heterogeneous set of E and S0 galaxies allows the Fundamental Plane to be studied (e.g. Jørgensen, Franx & Kjaergaard 1996).

5.4 SAURON $(V/\sigma, \varepsilon)$ diagram including 18 ‘specials’

In addition to the 48 E/S0 galaxies of the SAURON representative sample presented in Section 5.2, we observed 18 additional E/S0 galaxies with SAURON, using the same setup as for the main survey. For these galaxies, we extracted the stellar kinematics and measured the $(V/\sigma, \varepsilon)$ and λ_R using the same procedures and definitions as for the main sample (Section 4.4) and give the numerical values in Table 3. In Fig. 11, we show an extension of Fig. 9, where, in addition to the 48 galaxies of the SAURON survey, we also include the 18 specials. The new galaxies still populate the same regions as the galaxies from the main survey, confirming the result from that smaller sample. In particular, all the fast rotators still lie within the envelope defined by the δ - ε_{int} relation (the magenta line) and its variation with inclination, while the slow rotators lie in the bottom left part of the $(V/\sigma, \varepsilon)$ diagram. The five new slow rotators are on average flatter than the ones in the survey sample, but still fall within the same ranges of low ellipticity ($\varepsilon \lesssim 0.3$).

A notable exception is NGC 720 which is at the edge of being classified as a fast rotator (see Table 3), but is quite flat and lies well below the magenta line. This galaxy shows little rotation, but displays a clear and symmetric velocity pattern, with no kinematical misalignment and no sign of photometric twist (Peletier et al. 1990). All this indeed supports the classification of this galaxy as a fast rotator and would suggest that the slow rotation may be due to counter-rotating stellar components, as in the case of NGC 4473 and 4550 (Section 4.5). However, contrary to this hypothesis is the lack in NGC 720 of an elongation of the σ field along the galaxy major axis. Two-integral dynamical models using the Jeans equations (Binney, Davies & Illingworth 1990) already showed that part of the slow rotation in this galaxy must be in the form of a flattened velocity ellipsoid in the meridional plane [$\beta > 0$ i.e. DF not of the form $f(E, L_z)$]. This galaxy shows evidence from X-ray observations of being

Table 3. Measured parameters for the 18 E/S0 which are *not* part of the SAURON sample.

Notes. The meaning of the various columns is the same as in Table 1. Here, the effective radii R_e are mostly taken from RC3. Exceptions are NGC 221 for which R_e was taken from Paper IV, and NGC 2679, 6547 and 6548, for which R_e was determined from our MDM photometry.^aThese two galaxies show nearly face-on bars. The ellipticity represents the one of the outer disc, which also defines the photometric PA.

Figure 11. Same as Fig. 9 but for all the 66 E/S0 galaxies observed with SAURON (48 galaxies from the main survey plus 18 specials). The red diamonds and the blue circles refer to the slow and fast rotators, respectively. The filled symbols refer to the galaxies in the SAURON survey, while the open symbols indicate the 18 ‘special’ objects.

embedded in a triaxial dark matter halo (Romanowsky & Kochanek 1998; Buote et al. 2002) and the stellar component may be triaxial as well. Detailed three-integral Schwarzschild’s dynamical modelling is needed to clarify the nature of the orbital distribution in this interesting galaxy.

A key additional test provided by this extended sample concerns the shape distribution that we discussed in Section 5.1. In Fig. 12, we present a plot of the kinematical misalignment for the new sam-

Figure 12. Same as Fig. 8 but for the whole sample of 66 galaxies with existing SAURON stellar kinematics. Blue circles and red diamonds refer to the fast/slow rotators, respectively. The filled symbols refer to the galaxies in the SAURON survey, while the open symbols indicate the 18 ‘special’ objects. The morphology of NGC 2679 is dominated by a strong face-on bar, which explains the observed large misalignment. All the other new fast rotators are consistent with a family of nearly oblate bodies and show no significant kinematical misalignment.

ple of 18 galaxies, in addition to the SAURON sample. The sample of specials contains four additional slow rotators, NGC 4168, 4261, 4365 and 4406, which display a very clear rotation along the apparent minor axis and are certainly not oblate bodies [see Davies et al. (2001) and Statler et al. (2004) for a detailed discussion about NGC 4365, and also see van den Bosch et al. (2007)]. These new objects confirm that some of the slow rotators must be triaxial. A previous indication that large kinematic twists tend to appear only in the boxy slowly rotating galaxies was found by Kormendy & Bender (1996). The additional fast rotators still show no significant kinematical misalignment ($\Psi \lesssim 5^\circ$), the only exception being NGC 2679 which has a morphology dominated by the obvious oval shape of a nearly face-on bar. Even the face-on barred galaxy NGC 6548 has a kinematical PA which well agrees with the PA of the large-scale stellar disc. In total, out of 49 fast rotators presented in this paper, the only two that show significant kinematical misalignment, and are thus not consistent with axisymmetry, possess strong bars or show signs of recent interaction. This provides strong evidence that *all* the fast rotators constitute a homogeneous family of flattened and nearly oblate systems (sometimes with embedded bars).

5.5 Caveats

A number of caveats and possible improvements apply to the results we discussed in the previous sections:

Sample size and selection. The sample of E/S0 galaxies we consider in this paper is still relatively small and is not fully representative of the whole galaxy population. The modest size of the sample constitutes by far the largest limitation of the present study.

Field coverage. Although the available kinematics extend to larger distances and has higher signal-to-noise ratio than what was used in previous studies of the $(V/\sigma, \epsilon)$ diagram, it is still spatially limited and does not sample the whole galaxy, as would be required for a rigorous interpretation of the $(V/\sigma, \epsilon)$ diagram. The comparison between the modelling results, which treat the limited spatial coverage in detail, and the $(V/\sigma, \epsilon)$ results (Section 4.4), and the test with isotropic models (Appendix B), all indicate, however, a general agreement, suggesting the results are reliable. Another effect is that slow rotators tend to have larger R_e than the fast rotators. For this reason, the former are not spatially as well sampled as the latter. We verified that the conclusions would not change if we restricted our analysis to within $R_e/2$ for all galaxies.

Bars. The SAURON representative sample includes a number of barred galaxies. Since their complex structure and dynamics (e.g. Sellwood & Wilkinson 1993) cannot be represented in detail by oblate spheroids, and axisymmetric models likely provide only a very rough approximation, it is therefore unclear how bars affect correlations derived under the oblate assumption. Most strong bars must, however, have been rejected by the selection criteria for the 24 galaxy in our modelling subsample, so they are unlikely to be the primary driver behind the observed trend between β and ϵ_{intr} .

Triaxiality. The slow-rotating galaxies are likely weakly triaxial (de Zeeuw & Franx 1991) and the assumption of axisymmetry in our models certainly introduces a bias in the recovered anisotropy. As it appears that the triaxiality of these systems is not strong, at least in their central regions, the inferred anisotropy is likely to be representative of what we would measure from a full triaxial model (van den Bosch et al. 2007). A more detailed investigation of this issue will be presented in a future paper.

6 COMPARISON WITH PREVIOUS WORK

6.1 $(V/\sigma, \varepsilon)$ diagram from long-slit kinematics

In this section, we compare the results on the $(V/\sigma, \varepsilon)$ diagram derived from our SAURON integral-field stellar kinematics to previous results obtained from long-slit kinematics. The $(V/\sigma, \varepsilon)$ diagram from long-slit data of E galaxies was first presented and discussed by Illingworth (1977) and Binney (1978). It was later extended to galaxy bulges by Kormendy & Illingworth (1982). A widely known form of the diagram is the one presented in Davies et al. (1983), which is based on a compilation of long-slit kinematical measurements for 50 E galaxies and bulges. The compilation was extended by Bender et al. (1992) and many new observations were added by Bender et al. (1994). The largest homogeneous set of long-slit V/σ and ellipticity values is currently constituted by the 94 measurements for E galaxies by R. Bender (private communication). We will refer to this sample as that of Bender et al. (1994), although it was later extended with new unpublished measurements.

To perform a comparison between long-slit and integral-field V/σ measurements, one has to take into account that the two techniques measure two different quantities and cannot be compared in a rigorous way. From integral-field data, one measures a luminosity-weighted quantity (equation 10), which is closely related to the corresponding quantity appearing in the tensor virial equations and can be used directly in a quantitative way. From long-slit kinematics, one usually only measures the quantity V_{\max}/σ_0 , where V_{\max} is the maximum observed velocity (usually on the galaxy major axis), while σ_0 is an average value of the velocity dispersion inside $R_e/2$. This value cannot be linked to the expression appearing in the tensor virial equations without some rather arbitrary assumptions or ‘calibration’ with models.

From theoretical considerations, Binney (2005) provides a very rough connection between the two V/σ determinations. He shows that the long-slit V_{\max}/σ_0 measurements agree with the isotropic line, in the old formalism, if the isotropic line (his equation 9) is scaled by a factor of $\pi/4$ so that for an oblate isotropic galaxy $V/\sigma = 0.99$ at $\varepsilon = 0.5$. In his new integral-field formalism, the isotropic line is a factor of $\sqrt{2}$ lower (his equation 26) than that in the old one when $\alpha = 0$, so that for an oblate isotropic galaxy $V/\sigma = 0.89$ at $\varepsilon = 0.5$. For our adopted value $\alpha = 0.15$ (Appendix B), one has $V/\sigma = 0.79$ at $\varepsilon = 0.5$ so that the expected combined decrease from long-slit data to integral-field one would be a factor of $(V/\sigma)_e \sim 0.8 (V_{\max}/\sigma_0)$. However, as also pointed out by Binney (2005), the precise form of this equation depends on the detailed velocity distribution in a galaxy, as well as on the field coverage of the observations, and should not be expected to be quantitatively accurate. This was in fact his motivation to introduce a new formalism for integral-field data.

To avoid the approximations and assumptions in the above theoretical derivation, and to be able to compare directly our SAURON V/σ values with those measured with long-slit observations by Bender et al. (1994), we selected the 28 galaxies in common between the two samples and we determined the best scaling factor by least-squares fitting (Fig. 13). We found a best-fitting relation

$$\left(\frac{V}{\sigma}\right)_e \approx 0.57 \frac{V_{\max}}{\sigma_0}, \quad (23)$$

which is ~ 30 per cent lower than the above rough theoretical estimation. Although the differences in individual cases are not insignificant, there appears to be a general agreement between the SAURON and (scaled) long-slit V/σ determinations. The main ex-

Figure 13. Comparison between the SAURON integral-field $(V/\sigma)_e$ measurements and the corresponding V_{\max}/σ_0 values by Bender et al. (1994), corrected with equation (23) to make them comparable to integral-field observations.

Figure 14. Comparison between the luminosity-weighted values of ellipticity ε derived for the present paper and the corresponding ε_{B94} values by Bender et al. (1994).

ception are the galaxies with $V/\sigma \lesssim 0.1$, where the long-slit data tend to measure systematically smaller values. A comparison for the ellipticity values measured by us and by Bender et al. (1994) is shown in Fig. 14. There is a very good agreement between the ellipticities measured with our different methods.

In Fig. 15, we plot the 94 long-slit V/σ measurements by Bender, rescaled as in equation (23), and his corresponding ellipticity determinations, on top of the same lines as in Fig. 9. For the 28 galaxies

Figure 15. $(V/\sigma, \epsilon)$ diagram from long-slit kinematics. Same as Fig. 9 but for the 94 V_{\max}/σ_0 long-slit measurements and ϵ determinations by Bender et al. (1994). The V_{\max}/σ_0 values have been corrected with equation (23) to make them comparable to integral-field observations. For the 28 galaxies for which SAURON observations also exist, the arrows indicate the location on the diagram of the corresponding value of Fig. 11. The red and blue lines refer to the slow and fast rotators, respectively, classified according to the SAURON kinematics (Table 1).

in the Bender sample for which we have SAURON observations, we also show with an arrow the location of the corresponding SAURON V/σ and ϵ values. This plot shows that the use of integral-field data does not systematically change the distribution of galaxies on the $(V/\sigma, \epsilon)$ diagram. The differences between the SAURON $(V/\sigma, \epsilon)$ diagram and the one in Fig. 15 are discussed in the following section.

The comparison of this section shows that the long-slit observations already provided a reasonable approximation to the more rigorous V/σ that can be obtained from integral-field kinematics. However, integral-field kinematics provide many advantages over long-slit measurements for the study of the $(V/\sigma, \epsilon)$ diagram: (i) the dynamical models can only be uniquely constrained by integral-field kinematics; (ii) V/σ can be compared to the theoretical value in a rigorous way, without the need for an ad hoc scaling, allowing for a quantitative comparison with modelling results, in individual cases, as we did in Section 4.4; (iii) the ability to accurately determine the kinematical misalignment allows us to recognize the different shape distribution of the fast/slow rotators; (iv) the possibility to rigorously measure the specific angular momentum adds the crucial ability to distinguish between fast and slow rotators, independently from the $(V/\sigma, \epsilon)$ diagram itself (Paper IX). A proper kinematical classification of the galaxies is the key for the interpretation of the $(V/\sigma, \epsilon)$ diagram.

6.2 Sample selection effects on the $(V/\sigma, \epsilon)$ diagram

The comparison between the SAURON $(V/\sigma, \epsilon)$ diagram of Fig. 9 and the corresponding one by Bender et al. (1994) in Fig. 15 shows clear differences in the distribution of the observed galaxies. The

reason for these differences is easily understood as due to very different selection criteria in the two samples.

The early-type galaxies of the SAURON survey were selected to have an absolute blue magnitude $M_B \lesssim -18$, and in this luminosity range to include 24 objects in both the E and S0 morphological classes to be uniformly sampled in M_B and in the observed ellipticity (as given by de Vaucouleurs et al. 1991, hereafter RC3). By construction, this sample provides a uniform coverage of the $(V/\sigma, \epsilon)$ diagram, but does not give a representative sample of early-type galaxies in the given magnitude range. In fact, the true observed shape distribution of E/S0 galaxies displays a clear maximum at an ellipticity $\epsilon \approx 0.25$ and lacks very round and very flat galaxies (e.g. Lambas, Maddox & Loveday 1992). The requirement of a uniform sampling in ϵ obviously produces an excess of very round and very flat galaxies with respect to the general galaxy population. An additional complication arises from the fact that the SAURON selection was done according to the RC3 ellipticities, which are measured at large radii. The ellipticity in galaxies is generally not constant and its variation depends on galaxy luminosity, in the sense that luminous galaxies tend to become rounder in their central parts than in their outer parts (Ryden et al. 2001). The ϵ used in the $(V/\sigma, \epsilon)$ diagram are those measured in the central regions, where the kinematics are available, and not those of RC3. As a result of this, the SAURON selection produces a distribution in ϵ which is difficult to quantify.

Although the SAURON sample selection, by construction, erases any information given by the ϵ distribution, one may naively expect the distribution in V/σ for any given ϵ interval to be representative of the general E/S0 population, as no explicit selection was performed in V/σ . In practice, this is not the case because of the morphological selection, which implicitly introduces a selection on V/σ . In particular, Table 1 shows that out of the 24 galaxies classified as E from RC3, 14 (58 per cent) are classified as fast rotators and 10 (42 per cent) as slow rotators. For the S0 galaxies, 23 (96 per cent) are fast rotators and only one (4 per cent) is a slow rotator. Fig. 9 shows that the fast rotators tend to lie above the magenta line, at any given ϵ , while the slow rotators are in the bottom left part of the $(V/\sigma, \epsilon)$ diagram. This implies that the selection of S0 galaxies will guarantee objects above the magenta line in the $(V/\sigma, \epsilon)$ diagram, while E galaxies will provide an equal number of objects above the magenta line and in the bottom left part of the diagram. The morphological selection thus defines the allowed ranges of V/σ of any galaxy. The requirement of an equal number of E and S0 galaxies in every interval of ϵ specifies a certain distribution of galaxies in the $(V/\sigma, \epsilon)$ diagram, which is not representative of the early-type galaxies population. These selection biases are very difficult to estimate and to correct for from the present sample as they depend on the unknown distribution of fast/slow rotators as a function of intrinsic galaxy shape and morphological classifications.

The morphological selection also affects the appearance of the $(V/\sigma, \epsilon)$ diagram as obtained from the long-slit measurements by Bender et al. (1994). That sample is in fact constituted only by E galaxies. As originally pointed out by Davies et al. (1983), clearly stated by Kormendy & Bender (1996) and strongly confirmed in this paper and Paper IX, the E class constitutes a quite heterogeneous group, made by less than half of genuine non-rotating ellipticals (the slow rotators) and the rest by disc-like systems, resembling S0 galaxies (the fast rotators). The appearance of the $(V/\sigma, \epsilon)$ diagram of E galaxies thus depends on the fraction of fast rotators that are (mis)classified as E in different ϵ intervals. A direct comparison with the SAURON $(V/\sigma, \epsilon)$ diagram for the E galaxies alone (open circles) can be seen in Fig. 10. Although the SAURON sample has

only 25 per cent of the number of E of Bender et al. (1994), the distribution of the galaxies appears qualitatively similar.

The $(V/\sigma, \varepsilon)$ values for the E galaxies of Bender et al. (1994) in Fig. 15 span the same region as those of SAURON of Figs 9 or 11. However, there are three main qualitative differences between this diagram and the SAURON one, which can be understood as due to differences in the sample selection: (i) the E selection in the long-slit sample poses an upper limit on $\varepsilon \lesssim 0.5$, as otherwise the galaxies would be classified as S0. (ii) The lack of S0 in the long-slit sample implies a smaller fraction of fast-rotating galaxies (above the magenta line) compared to the SAURON $(V/\sigma, \varepsilon)$ diagram. (iii) The fact that there was no explicit selection on ε in the long-slit sample gives a smaller fraction of very round galaxies, compared to the SAURON sample. Moreover, older samples of V/σ values tend to prefer flatter E, as these were thought to be most likely to be seen edge-on, and consequently better consistent with the assumption of the $(V/\sigma, \varepsilon)$ diagram.

It is important to obtain an unbiased view of the $(V/\sigma, \varepsilon)$ diagram, from a larger statistical sample, to be able to compare the observed distribution of fast/slow rotators with the predictions from different galaxy formation scenarios. For this, one needs a sample which is only selected in absolute magnitude and is not biased by the morphological selection as the currently available samples. Some selection in morphological type is still required, as the $(V/\sigma, \varepsilon)$ diagram loses its meaning for spiral galaxies, which have a clear bulge and a thin disc component with very different ellipticity. However, contrary to the problematic classification into E or S0 galaxies, the separation between early-types galaxies and spirals is robust and clearly bimodal (Strateva et al. 2001; Baldry et al. 2004). Only with this larger and unbiased sample of E/S0 galaxies will we be able to understand whether the fast rotators all really fall within the envelope indicated by the current study, and whether the distribution of the slow/fast rotators shows a bimodality in the $(V/\sigma, \varepsilon)$ diagram, as the current data seem to suggest.

6.3 Spurious increase in anisotropy of slow rotators?

In Section 6.2, we showed that our SAURON data on the $(V/\sigma, \varepsilon)$ diagram are generally consistent with previous long-slit works. The current study, however, seems inconsistent with previous studies (e.g. Davies et al. 1983; Binney & Tremaine 1987; Kormendy & Bender 1996) in its finding that the massive and slowly rotating galaxies are *not* more anisotropic than the generally fainter and fast-rotating galaxies (e.g. Fig. 6).

Part of the difference between the current work and the previous ones may lie in the sample selection, which here includes S0 galaxies, as they cannot be distinguished from the other fast rotators. The rest can be understood as due to (i) the use of the parameter $(V/\sigma)^*$ as a measure of galaxy anisotropy and (ii) the neglect of inclination effects on the $(V/\sigma, \varepsilon)$ diagram.

The anisotropy parameter was defined by Kormendy (1982b), Davies et al. (1983) and Bender & Nieto (1990) as

$$(V/\sigma)^* \equiv \frac{V/\sigma}{(V/\sigma)_{\text{iso}}}, \quad (22)$$

i.e. the ratio between the observed V/σ value for a galaxy and the predicted value $(V/\sigma)_{\text{iso}}$ for an oblate galaxy with isotropic velocity dispersion tensor (Binney 1978). As pointed out by Binney (2005), $(V/\sigma)^*$ is not a reliable way of measuring anisotropy in a galaxy and should be replaced by the real anisotropy value δ . The problems of $(V/\sigma)^*$ as a measure of anisotropy δ are the following: (i) galaxies with the same δ but with different intrinsic ellipticity ε_{int} can appear

Figure 16. Top panel: $(V/\sigma, \varepsilon)$ diagram. The meaning of the solid lines is as in Fig. 9. The blue diamonds and red squares represent the location of edge-on galaxies, with different intrinsic ellipticity ε_{int} but the same anisotropy $\delta = 0.1$. The red ellipse indicates the region where the slow rotators are generally observed (Figs 9 and 15). Bottom panel: location of the galaxies of the top panel in the $[\log(V/\sigma)^*, \varepsilon]$ diagram. The diamonds and squares represent galaxies with the same small anisotropy, so one should expect $\log(V/\sigma)^* \approx 0$. There is, however, a dramatic decrease of $\log(V/\sigma)^*$ for the objects which fall close to the region of the slow rotators (red squares), which is not associated to any variation in the anisotropy.

to have dramatically different $(V/\sigma)^*$ when seen edge-on, and even more different $\log(V/\sigma)^*$. In particular, the rounder galaxies will have a systematically lower $(V/\sigma)^*$ at any given δ (Fig. 16). (ii) A galaxy with a given δ and ε_{int} will appear to have a lower $(V/\sigma)^*$ at lower inclinations ($i = 90^\circ$ being edge-on) as shown, for example, in Fig. 9 (see also Burkert & Naab 2005).

The slow rotators generally have observed ellipticities $\varepsilon \lesssim 0.3$ (Figs 9 and 15), which implies they are intrinsically not very flat. The fast rotators can be intrinsically flat. Given this difference in the shape of the fast and slow rotators, both the ellipticity and inclination effects mentioned in the previous paragraph act to systematically decrease the observed $(V/\sigma)^*$ of the slow rotators with respect to the fast rotators, giving the misleading impression of a strong increase of the anisotropy. We conclude that $(V/\sigma)^*$ should not be used as a measure of anisotropy. Interestingly, however, $(V/\sigma)^*$ still contains useful information on the galaxies dynamical status. In fact, $(V/\sigma)^*$ is nearly constant along the magenta line of Fig. 9, and the fast rotators generally satisfy $(V/\sigma)^* \gtrsim 0.4$.

7 DISCUSSION

7.1 Early-type galaxies in the nearby universe

Observations at high redshift, combined with detailed measurements of the cosmic microwave background, have provided a scenario for galaxy formation in which the Universe is dominated by dark matter of unknown nature. The general picture for the assembly of the dark matter seems to be rather well understood and is described by a hierarchical process driven by the sole influence of gravity (e.g. Springel et al. 2005b). Much, however, still has to be learned about the way the luminous matter, namely the stars and galaxies that we actually observe, form from the accretion of gas within the dark matter potential. The complication comes from the fact that these processes are driven by the hydrodynamic and chemistry of the gas, combined with complex feedback processes of the radiation on it.

One way to constrain the formation of the luminous matter in galaxies is by trying to uncover the ‘fossil record’ of that process in nearby galaxies, which can be observed in great detail due to their vicinity. A key element to differentiate between different galaxy formation models is the degree of anisotropy and the amount of rotation in early-type galaxies, in relation to other galaxy properties such as luminosity, surface brightness profiles or chemical composition (e.g. Binney 1978; Davies et al. 1983). Observations show that early-type galaxies can be broadly separated into the most massive giant ellipticals on one side, which are red, metal rich, slowly rotating and have shallow central photometric profiles, and the fainter objects on the other side, which tend to be bluer, metal poor, are dominated by rotation, have cuspy profiles and may contain discs (Davies et al. 1983; Jaffe et al. 1994; Kormendy & Bender 1996; Faber et al. 1997; Lauer et al. 2005).

A first factor determining these observed differences in the structure of early-type galaxies appears to be the amount of dissipation during the last galaxy merger. In particular, more anisotropic and slowly rotating galaxies result from predominantly collisionless major mergers, while faster rotating galaxies are produced by more gas-rich mergers, where dissipation plays an important role (Kormendy 1989; Bender et al. 1992; Faber et al. 1997). The prevalence of gas-poor mergers in the hierarchical formation of massive galaxies (Khochfar & Burkert 2005) would help explain the fact that slowly rotating galaxies are more common in the high-mass galaxy range. A second factor driving the galaxy structure seems to be the mass fraction of the merger components. Equal-mass galaxy mergers tend to produce more slowly rotating galaxies than mergers of significantly different mass ratio (Naab, Burkert & Hernquist 1999; Naab & Burkert 2003). A third factor appears to be the feedback on the gas, during a merger event, produced by the radiation emitted by a central active galactic nucleus (AGN) or by supernovae winds (e.g. Granato et al. 2004; Springel, Di Matteo & Hernquist 2005a).

A complete understanding of the formation of early-type galaxies, and the relative role of the different factors, requires the treatment of the above phenomena in a cosmological context, within the hierarchical merging process. This still has to be attempted in a rigorous way as current computer simulations cannot resolve the many orders of magnitude scales that are involved in these processes. This implies that instead of describing the gas via accurate hydrodynamical and radiative transfer equations, the models use approximate and very simple relations, based on empirical relations, to describe the process. This paper and the companion paper (Paper IX) provide new observational constraints for the upcoming models. In the next

section, we speculate on the formation scenarios for the observed characteristics of early-type galaxies that we derived.

7.2 Nature of the fast and slow rotators

The fast rotators seem consistent with galaxies with a significant disc component, which experienced minor mergers and accreted a significant amount of gas (Naab et al. 1999; Naab & Burkert 2003; Bournaud, Jog & Combes 2005; Cox et al. 2006; Novak et al. 2006; Jesseit et al. 2007). The accreted gas, which settles in the galaxy equatorial plane and forms stars, would explain the metallicity enhancement in the plane of the disc (Paper VI) and the nearly perfect alignment of the angular momentum of the different, sometimes counter-rotating, stellar structures (Section 4.5). The minor mergers may explain the fact that rounder galaxies have a larger σ_z dispersion orthogonal to the disc plane (along the z -axis). The disc instabilities triggered by minor mergers can in fact deviate stellar orbits out of the disc plane and produce an increase in the σ_z dispersion and a corresponding thickening of the disc. The trend may also be related to the two-component nature of the fast rotators. Discs may be more anisotropic than bulges and are more prominent in flat galaxies (Section 5.3). Numerical simulations seem able to produce the observed level of anisotropy in these systems (Burkert & Naab 2005), but it is unclear for what conditions they will reproduce the observed trend between anisotropy and flattening.

Although we do not find any physical distinction between E fast rotators with discy isophotes and S0 fast rotators with an obvious disc component, and this suggests a common formation scenario for the whole class of objects, the current observations do not necessarily require a common origin. Different formation paths are possible like the formation of discy E fast rotators via gas acquisition from a slow rotator E galaxy, or major gas-rich mergers, and S0 fast rotators from gas starvation of spiral galaxies.

Originally, the slow rotators were thought to form at high redshift via equal-mass mergers of disc galaxies (Barnes 1988). The N -body simulations were able to produce some slowly rotating systems that appeared like ellipticals; however, it became clear that this simple picture could not explain the observed appearance of slowly rotating ellipticals as a class (Hernquist 1992; Naab & Burkert 2003). In addition, current numerical simulations of gas-free major mergers seem to generate large fractions of strongly triaxial or prolate galaxies ($0.2 \lesssim \varepsilon \lesssim 0.6$) than we do *not* observe (e.g. Boylan-Kolchin, Ma & Quataert 2005; Burkert & Naab 2005; González-García & van Albada 2005; Cox et al. 2006). A missing ingredient in these models is the cosmological context, which produces sequences of mergers. Also lacking is a detailed treatment of the gaseous component, which is likely to play an important role in the early universe (e.g. Ciotti, Lanzoni & Volonteri 2007). Major gas-rich mergers, regulated by the feedback of a powerful central AGN, have been suggested to explain the scaling relations of early-type galaxies (Robertson et al. 2006) and to reproduce the dichotomy (e.g. Faber et al. 2005; Cattaneo et al. 2006) in the colour distribution of galaxies as a function of their luminosity (Strateva et al. 2001; Baldry et al. 2004).

It is unclear why the slow rotators in our sample possess the low degree of anisotropy that we observe in their central regions. A process that could in principle explain both the relatively small anisotropy and the roundish shape of the slow rotators would be the global transition to chaos, as can be produced by central supermassive black holes (Merritt & Fridman 1996). Current estimates of black hole’s mass fractions (Håring & Rix 2004) seem, however, too small to produce significant effects. The transition to chaos and the symmetrization of the triaxial major-merger remnant could be

significantly enhanced by the gas inflow and its nuclear concentration during the initial phase of the mergers, before the gas is expelled from the galaxies by the AGN activity (Barnes 1988). Another process that could explain the isotropy and shape of the slow rotators, especially for the most massive galaxies found near the centre of cluster potentials, is a sequence of radial mergers (Cooray & Milosavljević 2005).

7.3 Connection with higher redshift observations

The detailed observations of the structure of the small sample of nearby galaxies that we discuss can be related to much less detailed observations at higher redshift obtained with much larger survey. From the analysis of a large sample of galaxies in the nearby universe, observed by the Sloan Digital Sky Survey, it was found that galaxies are well distinct in terms of their colour, in the sense that they can be clearly separated in a so-called ‘blue cloud’ and a ‘red sequence’ (Strateva et al. 2001; Baldry et al. 2004). This discovery, and the subsequent realization that the bimodality can be traced back in time at higher and higher redshift (Bell et al. 2004), allowed a dramatic improvement in the detailed testing of galaxy formation scenarios. It is now believed that the gas-free and dead, red-sequence galaxies form by merging of gas-rich, star-forming, blue-cloud galaxies, followed by a rapid ejection of the gas, due to the feedback from a central supermassive black hole (e.g. Faber et al. 2005). In a merger event between blue gas-rich galaxies, the gas tends to settle on to a plane and form a disc, so that the end result of the merger, after the gas has been expelled from the system, will be a red, purely stellar system dominated by rotation. But mergers can still happen between red gas-poor galaxies, in which case simulations show that the resulting red galaxy will show little or no rotation.

We speculate that the two classes of fast- and slow-rotating galaxies that we described may be the relics of the different formation paths followed by early-type galaxies when losing their gas content and moving from the ‘blue cloud’ to the ‘red sequence’, in the ‘quenching’ scenario of Faber et al. (2005). In that picture, the fast rotators are naturally associated with the spiral galaxies whose discs were quenched by ram-pressure stripping or other ram-starvation processes, and subsequently experienced mainly minor mergers. The slow rotators can be generated by a sequence of mergers involving little amount of gas along the red sequence, or due to major violent gas-rich mergers in which the gas component was rapidly expelled by a starburst or a central AGN.

8 CONCLUSIONS

We analysed the orbital distribution of E and S0 galaxies using observations of the stellar kinematics within one effective (half-light) radius obtained with the SAURON integral-field spectrograph. We constructed the $(V/\sigma, \varepsilon)$ diagram for the 48 E/S0 of the SAURON sample. For a subsample of 24 of the galaxies, consistent with axisymmetry, we use three-integral axisymmetric Schwarzschild models to recover the detailed orbital distribution.

We used a new classification of early-type galaxies based on the stellar kinematics (Paper IX) to divide the sample into two classes of objects with and without a significant amount of angular momentum per unit stellar mass. We refer to these two types of object as ‘slow rotators’ and ‘fast rotators’, respectively. The slow rotators are more common among the brightest systems, and are generally classified as E from photometry alone. The fast rotators are generally fainter and are classified as either E or S0.

From the combined analysis of the dynamical models and the $(V/\sigma, \varepsilon)$ diagram, we find that in the central regions (within $\sim 1R_c$) of the galaxies which we sample with our kinematics:

(i) the slow rotators can display misalignment between the photometric and kinematic axes, indicating that as a class they are triaxial. Those in our sample tend to be fairly round ($\varepsilon \lesssim 0.3$), and span a range of moderate anisotropies (Binney 1978 anisotropy parameter $\delta \lesssim 0.3$).

(ii) the fast rotators can appear flattened ($\varepsilon \lesssim 0.7$), do not show significant kinematical misalignment (unless barred or interacting), which indicates they are all nearly axisymmetric, and span a large range of anisotropies ($\delta \lesssim 0.5$). *The main physical difference between fast and slow rotators is not their degree of anisotropy, but their intrinsic shape.*

(iii) the measured anisotropy appears to be due to a flattening of the velocity ellipsoid in the meridional plane ($\sigma_R > \sigma_z$), which we quantify with the β anisotropy parameter, while the velocity dispersion tends to be similar along any direction orthogonal to the symmetry axis ($\sigma_R \sim \sigma_\phi$).

(iv) we find a general trend between the anisotropy in the meridional plane β and the galaxy intrinsic ellipticity $\varepsilon_{\text{intr}}$. Flatter galaxies tend to be more anisotropic.

(v) the results from the models are consistent with the values of the anisotropy inferred from the $(V/\sigma, \varepsilon)$ diagram of the whole SAURON sample of 48 E/S0, which we determined from our integral-field kinematics. We find that the distribution of the fast-rotating galaxies is well described as a family of nearly oblate galaxies following a trend between flattening and anisotropy. This result is confirmed when we include in the sample 18 additional E/S0 galaxies observed with SAURON.

Although the sample of early-type galaxies considered in this work constitutes the first significant sample for which the $(V/\sigma, \varepsilon)$ diagram and the anisotropy could be investigated with integral-field stellar kinematical data, the main limitation of our work is the relatively small number of galaxies and the complicated sample selection effects. Even so, as we discussed in Section 7, we are able to reach some provisional conclusion on the formation of early-type galaxies. We reviewed the usefulness of the $(V/\sigma, \varepsilon)$ diagram to test galaxy formation models. A similar analysis, performed on a much larger sample of galaxies, could provide much stronger constraints on the process by which galaxies form.

ACKNOWLEDGMENTS

We thank Andi Burkert and Marijn Franx for very useful comments, Ralf Bender for providing his latest long-slit $(V/\sigma, \varepsilon)$ measurements and Ortwin Gerhard for providing his numerical values of the anisotropy. We thank the referee, John Kormendy, for a detailed report which helped in significantly improving the presentation of our work. The SAURON project is made possible through grants 614.13.003, 781.74.203, 614.000.301 and 614.031.015 from NWO and financial contributions from the Institut National des Sciences de l’Univers, the Université Claude Bernard Lyon I, the Universities of Durham, Leiden, and Oxford, the British Council, PPARC grant ‘Extragalactic Astronomy & Cosmology at Durham 1998–2002’, and the Netherlands Research School for Astronomy NOVA. MC acknowledges support from a VENI award (639.041.203) by the Netherlands Organization for Scientific Research (NWO) and a PPARC Advanced Fellowship (PP/D005574/1). RLD is grateful for the award of a PPARC Senior Fellowship (PPA/Y/S/1999/00854) and postdoctoral

support through PPARC grant PPA/G/S/2000/00729. The PPARC Visitors grant (PPA/V/S/2002/00553) to Oxford also supported this work. JFB acknowledges support from the Euro3D Research Training Network, funded by the EC under contract HPRN-CT-2002-00305. GVDV acknowledges support provided by NASA through grant NNG04GL47G and through Hubble Fellowship grant HST-HF-01202.01-A awarded by the Space Telescope Science Institute, which is operated by the Association of Universities for Research in Astronomy, Inc., for NASA, under contract NAS 5-26555. Photometric data were obtained (in part) using the 1.3-m McGraw-Hill Telescope of the MDM Observatory. The SAURON observations were obtained at the William Herschel Telescope, operated by the Isaac Newton Group in the Spanish Observatorio del Roque de los Muchachos of the Instituto de Astrofísica de Canarias. This research has made use of the NASA/IPAC Extragalactic Data base (NED). We acknowledge the usage of the HyperLeda data base (<http://leda.univ-lyon1.fr>).

APPENDIX A: TESTING ANISOTROPY WITH TWO-INTEGRAL MODELS

The three-integral axisymmetric models of Section 4.1 show that, in the central regions that we constrain with our integral-field kinematics, (i) the flatter fast rotators are anisotropic, in the sense that their velocity ellipsoid is flatter along the direction of the symmetry axis than along the radial direction $\sigma_z < \sigma_R$; (ii) the rounder slow rotators are nearly isotropic. In this section, we do a qualitative test of the consistency and robustness of these statements with the results of two-integral Jeans models. This test uses a very different and simpler modelling method and a different kinematics extraction. It allows us to verify the robustness of our results against implementation and observational details.

The Jeans models we use assume axisymmetry, constant M/L and a stellar DF of the form $f = f(E, L_z)$, where E is the energy and L_z is the angular momentum along the symmetry axis z . From the same MGE parametrization of the surface brightness used in the Schwarzschild models (Section 3) and an estimate of the central black-hole mass, we compute the unique predictions for the velocity second moments μ_2 , at the best-fitting inclination, using the formalism of Emsellem et al. (1994) (see Paper IV for more details). The second velocity moments were extracted from the SAURON kinematics as $\mu_2 \equiv \sqrt{V^2 + \sigma^2}$, where V and σ are the mean velocity and the velocity dispersion used also in the $(V/\sigma, \varepsilon)$ diagram (Section 2).

A1 Anisotropy of the flat fast rotators

To test the anisotropy of the flat fast rotators, we consider the three galaxies NGC 821, 3377 and 4660, which are constrained by the observed photometry to be close to edge-on. This choice reduces the non-uniqueness in the mass deprojection (Rybicki 1987) and

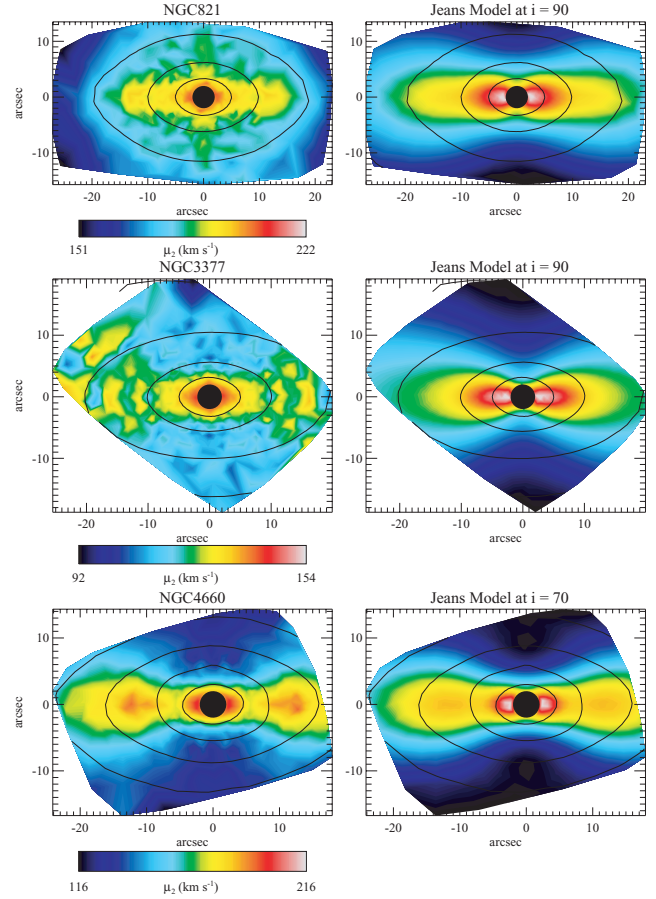

Figure A1. Jeans models of flattened galaxies. Left-hand panels: bi-symmetrized and linearly interpolated maps of the observed second velocity moment $\mu_2 \equiv \sqrt{V^2 + \sigma^2}$, measured from the SAURON stellar kinematics of the galaxies NGC 821, 3377 and 4660. The actual Voronoi bins in which the kinematics were measured are shown in Paper III. All three galaxies are quite flattened and are constrained by the observed photometry to be close to edge-on. Right-hand panels: two-integral Jeans modelling of the unique projected second moments associated to the MGE mass density distribution, at the best-fitting inclination from Paper IV. In all three cases, the models show a larger difference between the μ_2 measured along the major and minor axes than is observed.

correspondingly the possible degeneracies in the deprojection of the higher velocity moments. These three galaxies have a σ field well resolved by the SAURON instrumental resolution. For edge-on galaxies, one does not have any direct measurement of the component of the velocity dispersion σ_z parallel to the symmetry axis; however the flattening of the velocity ellipsoid is tightly constrained if the galaxy is assumed to be axisymmetric and in equilibrium [same as in the $(V/\sigma, \varepsilon)$ diagram]. Nearly edge-on galaxies are thus ideal for our test.

The comparison with the Jeans model predictions is shown in Fig. A1. The models provide a reasonable first-order description of the observations; however significant systematic deviations exist. This indicates that, assuming the mass traces the light, the modelled galaxies do not have a DF of the form $f(E, L_z)$. In particular, a common characteristic of models is that for all three galaxies they predict too much motion (high μ_2 values) along the galaxies projected major axis with respect to the minor axis. Any two-integral $f(E, L_z)$ model has a velocity ellipsoid which appears circular in cross-section with the meridional plane ($\sigma_R = \sigma_z$ and $\langle v_z v_R \rangle = 0$).

Figure A2. Jeans models of nearly round galaxies. The open squares with error bars represent the observed second velocity moment $\mu_2 \equiv \sqrt{V^2 + \sigma^2}$, measured from the SAURON stellar kinematics of the galaxies NGC 4374, 4486 and 4552. The values and errors have been computed as the biweight mean and standard deviation of the kinematics extracted from the Voronoi bins within circular annuli. The solid line shows the second velocity moment computed from two-integral Jeans models. The dashed vertical line shows the region where the SAURON field provides a full spatial coverage of the galaxy. This is the region visualized in Fig. 1 and from which the mean anisotropy was estimated. The two-integral models provide a very good description of the data within the central region. Given the near spherical symmetry, the models are almost fully isotropic in the central regions.

The observed difference between models and observations indicates that the real galaxies have a larger velocity dispersion than the models, along the R direction, orthogonally to the z symmetry axis. This implies that the velocity ellipsoid must be on average elongated in the R direction. In this way, for nearly edge-on galaxies, the observer sees a larger component of the dispersion along the minor axis, when the radial direction in the galaxy is parallel to the line-of-sight, than along the major axis. A similar finding was interpreted by van der Marel (1991) as evidence of radial anisotropy and the same reasoning applies in our case.

A2 Near isotropy of the round slow rotators

To test the near isotropy inferred using three-integral models for the rounder slow rotators of the modelling subsample, we selected the three apparently quite round galaxies NGC 4374, 4486 and 4552.

These three galaxies have none or very little evidence for rotation, and the velocity dispersion field presents a nearly circular symmetric distribution (Paper III). We constructed axisymmetric $f(E, L_z)$ Jeans models as in the previous section, taking into account the apparent flattening of the galaxies in the outer regions; however, given the near-spherical shape in the central regions, the models are almost fully isotropic with $f = f(E)$. It is sufficient to compare data and models along circular rings.³ The SAURON data were averaged by computing a biweight mean and standard deviation (Hoaglin, Mosteller & Tukey 1983) of the values extracted from the Voronoi bins within radial ranges. The use of integral-field kinematics provides radial profiles of μ_2 with very small scatter.

If the galaxies were nearly isotropic in their central regions, as the Schwarzschild models show, the simple Jeans models, with only M/L as free parameter, should provide a good representation of the observed μ_2 profiles. The comparison between the μ_2 profiles of the data and the isotropic models (Fig. A2) shows that indeed the models generally reproduce the data within the small uncertainties, and confirms the consistency of the observed galaxies with a nearly isotropic orbital distribution. The galaxies are of course not perfectly isotropic: deviations between data and model do exist, particularly in the outer regions of NGC 4486, and these small deviations from isotropy are consistent with the location of the galaxies below the isotropy line in the $(V/\sigma, \epsilon)$ diagram (Fig. 9).

APPENDIX B: TESTING THE $(V/\sigma, \epsilon)$ DIAGRAM WITH ISOTROPIC MODELS

For a quantitative use of the $(V/\sigma, \epsilon)$ diagram, three questions have to be answered: (i) can one measure reliable values of the anisotropy using the $(V/\sigma, \epsilon)$ diagram from integral-field kinematics with limited spatial coverage? (ii) Can one derive realistic anisotropies for models with an ellipticity that varies as a function of radius? (iii) What is the value for the parameter α (equation 14) appropriate for realistic galaxy models?

We tried to address some of these questions in Section 4.4 by comparing the anisotropy derived from the Schwarzschild models with the one measured with the $(V/\sigma, \epsilon)$ diagram. The good agreement between the two determinations showed that the answer to the first two questions is positive. These tests allowed us to verify the reliability of the $(V/\sigma, \epsilon)$ diagram for a wide range of anisotropies. However, the approximate nature of the orbit-superposition models does not allow the test to be carried out very accurately.

An alternative would be to use analytic models. The limitation of these tests is that they are easy to carry out only in the isotropic case. This was done by Binney (2005) who also concluded with a positive answer to the first two questions above. In addition, he measured a value of $\alpha \lesssim 0.2$ for his test cases. However, his adopted models were not entirely realistic, so the results cannot be necessarily generalized to real galaxies.

In this section, we revisit what was done by Binney (2005) using the MGE models to approximate in detail the surface brightness of actual galaxies. For this test, we selected five galaxies which represent some of the different types found in our SAURON sample and for which we derived a nearly edge-on inclination in Paper IV. The galaxy NGC 4486 is a giant E with the largest σ_e in our sample. It shows no sign of rotation and has a nuclear cuspy core in

³ The two-dimensional data versus model comparison for NGC 4552 was presented in fig. A1 of Paper IV.

the surface brightness profile. NGC 4552 and 5831 are also classified as slow rotators and have central cuspy cores. NGC 3377 and 4621 are classified as fast rotators, are coreless and have discy isophotes.

We computed the projected V and σ fields for the five galaxies under the assumption of axisymmetry and self-consistency (i.e. constant M/L). In this case, when the DF is assumed to be a function $f(E, L_z)$ of the two classical integrals of motion, the energy E and the angular momentum L_z with respect to the symmetry axis, the non-centred second moment μ_2 is uniquely defined by the density, once the inclination i and the M/L are chosen (Lynden-Bell 1962; Hunter 1977). If in addition one assumes isotropy of the velocity dispersion tensor, then the first moment μ_1 of the velocity is also uniquely specified. Both moments μ_1 and μ_2 can be computed by solving the Jeans and Poisson equations (e.g. Satoh 1980; Binney et al. 1990). In the case the density is described by the MGE parametrization, the moment μ_1 , projected on the sky plane, can be evaluated as a double integral using equation (59) of Emsellem et al. (1994). The projected moment μ_2 is evaluated as a single integral via equation (61) of the same paper (corrected for a typo as in Paper IV). We made the standard approximate identification $V \equiv \mu_1$ and $\sigma^2 \equiv \mu_2^2 - \mu_1^2$.

To be able to measure the parameter α , the MGE models need to have constant ellipticity as a function of radius, as the adopted form of the $(V/\sigma, \varepsilon)$ diagram precisely applies only in that case. For this, we took the MGE parameters as given in Paper IV but we set all the ellipticities ε equal to a constant value $\varepsilon = 0.2, 0.4, \dots, 0.8$. In this way, the new MGE models have the same realistic major axis profile of the original galaxy, but have constant ε . To evaluate the Jeans equations in a computationally efficient and accurate way up to large radii, and even for very flat models, we computed them on a grid linear in the logarithm of the elliptical radius and in the eccentric anomaly. This was done by defining a logarithmically spaced radial grid r_j and then computing the moments at the coordinate positions $(x_{j,k}, y_{j,k}) = [r_j \cos \theta_k, r_j(1 - \varepsilon) \sin \theta_k]$ for linearly spaced θ_k values. The model was then re-interpolated on to a fine Cartesian grid for the estimation of the V/σ as done on the real integral-field data.

In Fig. B1, we show the location of the five isotropic galaxy models on the $(V/\sigma, \varepsilon)$ diagram. In the top plot, the V/σ was measured from the model by integrating it within an ellipse of ellipticity ε having mean radius $R_* \equiv a\sqrt{1 - \varepsilon} = 3R_e$, where a is the semimajor axis of the ellipse. For each different ε , the five models have similar V/σ value and they lie along the theoretical isotropic line if one adopts $\alpha \approx 0.20 \pm 0.03$. In the second panel, the V/σ was measured within an ellipse of mean radius $R_* = R_e$, which closely resemble what we are doing on the real SAURON data. In this case, the models lie slightly below the isotropic line, but the inferred anisotropy is still negligible $\delta \lesssim 0.1$. This shows that an ellipse of mean radius R_e is still sufficient for a reliable recovery of the V/σ value of realistic galaxy models. This is not the case when the V/σ is measured within an ellipse of mean radius $R_* = R_e/2$, as in this case the values start being significantly underestimated ($\delta \gtrsim 0.2$, third panel). In the bottom panel, the V/σ was measured within circles of radius R_e . The V/σ values are now significantly below the isotropic line, particularly for very flattened models, and this shows that in the case of finite spatial coverage the V/σ should be preferably evaluated along flattened ellipses than along circles.

To test the reliability of the $(V/\sigma, \varepsilon)$ diagram in a more realistic case of variable ellipticity, we computed the $(V/\sigma, \varepsilon)$ values inside $1R_e$ from isotropic models of the five test galaxies computed without modifying the ellipticities of the Gaussians in the MGE models of Paper IV. The ε used is the one measured on the real galaxies.

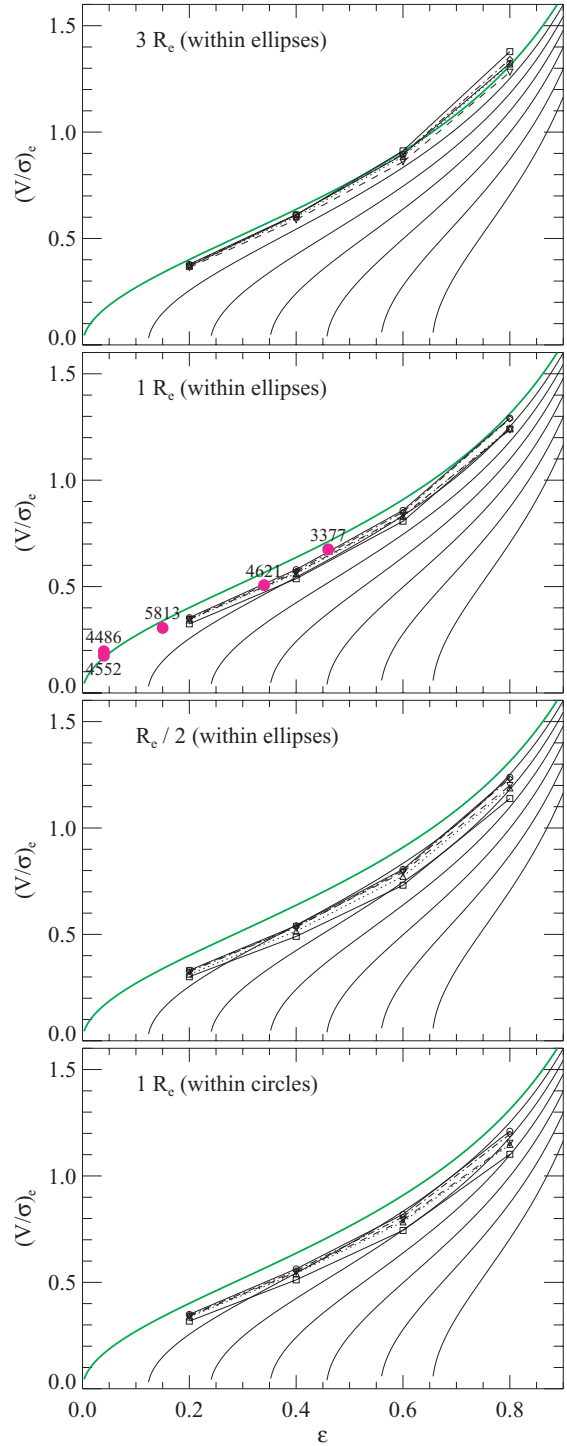

Figure B1. V/σ of edge-on isotropic galaxy models. Top plot: the V/σ was measured from the model by integrating it within an ellipse of ellipticity ε and mean radius $R_* \equiv a\sqrt{1 - \varepsilon} = 3R_e$, where a is the semimajor axis of the ellipse. Different lines and symbols correspond to the five different MGE galaxy models discussed in the text, with constant ε . Second panel: the V/σ was measured within an ellipse of mean radius $R_* = R_e$. The filled circles with NGC numbers refer to the $(V/\sigma, \varepsilon)$ values measured on the edge-on isotropic models with the observed variable ε . Third panel: V/σ within an ellipse of mean radius $R_* = R_e/2$. Bottom panel: the V/σ was measured within circles of radius R_e . This plot shows that V/σ is better recovered along ellipses than along circles of the same area. Moreover, the V/σ values appear to be well recovered within an ellipse of mean radius at least R_e .

The result of this test is shown in the second panel of Fig. B1. It shows that the $(V/\sigma, \varepsilon)$ values extracted from isotropic models of realistic galaxies, extracted within $1R_e$, do lie close to the theoretical isotropic line for oblate galaxies (when $\alpha \sim 0.2$).

APPENDIX C: MONTE CARLO SIMULATION

In Section 5.2, we showed that the location occupied by the fast-rotating galaxies in the SAURON representative sample is consistent with the one expected according to equation (19). It is, however, unlikely that galaxies will follow a correlation with zero scatter. Moreover, the previous discussion does not make use of the information contained in the whole distribution of observed galaxies in the $(V/\sigma, \varepsilon)$ diagram. As we do not know the inclination for all the galaxies in the sample, the only way to verify if the observed measurements imply a correlation between shape and anisotropy is to resort to Monte Carlo simulations.

We saw in Section 5.1 that the fast rotators are consistent with being a population of nearly oblate galaxies. In principle, under the oblate hypothesis, it is possible to invert the observed ellipticity distribution to derive the intrinsic shape distribution, under the assumption of random orientations. However, the SAURON sample was explicitly selected to cover a nearly uniform range of ellipticities (Paper II), and this means that (i) one cannot assume random orientations and recover the intrinsic distribution, and (ii) the observed distribution on the $(V/\sigma, \varepsilon)$ diagram will be weakly dependent on the assumed ellipticity distribution, once the same selection criteria are applied. For this reason, while still assuming the fast rotators are oblate, we will adopt the parametric form for the distribution of intrinsic ellipticities derived by Lambas et al. (1992) for a sample of ~ 5000 S0 galaxies:

$$\phi(\varepsilon_{\text{intr}}) = \begin{cases} \frac{1}{\sigma_\varepsilon \sqrt{2\pi}} \exp\left[-\frac{(\varepsilon_{\text{intr}} - \varepsilon_0)^2}{2\sigma_\varepsilon^2}\right] & \text{if } 0 \leq \varepsilon_{\text{intr}} \leq 0.65 \\ 0 & \text{otherwise,} \end{cases} \quad (\text{C1})$$

with $\varepsilon_0 = 0.41$ and $\sigma_\varepsilon = 0.24$, and where we set an upper limit on $\varepsilon_{\text{intr}}$ based on the maximum ellipticity observed in our sample.

For any given ellipticity, we *assume* a simple linear relation with slope m_δ to determine the anisotropy, as found in Section 4.6, but we allow for an intrinsic (Gaussian) scatter around the relation. The distribution of the anisotropy δ at any given ellipticity is then assumed to be

$$\phi(\delta) = \begin{cases} \frac{1}{\sigma_\delta \sqrt{2\pi}} \exp\left[-\frac{(\delta - m_\delta \varepsilon_{\text{intr}})^2}{2\sigma_\delta^2}\right] & \text{if } 0 \leq \delta \leq \frac{\Omega - 1}{\Omega} \\ 0 & \text{otherwise,} \end{cases} \quad (\text{C2})$$

where the upper limit for δ comes from the condition $(V/\sigma)^2 \geq 0$ in equation (14) and $(m_\delta, \sigma_\delta)$ are two free parameters.

Given $\varepsilon_{\text{intr}}$ and δ , we use the inverse of equation (14) to compute the edge-on V/σ value. Finally, with equations (12) and (13) we project the $(V/\sigma, \varepsilon_{\text{intr}})$ pair of values to get the observed $[(V/\sigma)_{\text{obs}}, \varepsilon]$, assuming a uniform distribution on the sphere of the viewing angles (i.e. a uniform probability distribution in $\sin i$). This process, repeated for a large number ($\sim 10^8$) of random realizations of the $\varepsilon_{\text{intr}}$ variable, is used to compute a histogram. This constitutes a numerical estimate of the probability $P[(V/\sigma)_{\text{obs}}, \varepsilon; m_\delta, \sigma_\delta]$ of observing a galaxy within a certain range of values on the $(V/\sigma, \varepsilon)$ diagram, for any given set of our two model parameters $(m_\delta, \sigma_\delta)$.

One complication now arises because of the SAURON selection criteria. We need to consider the fact that the value of $\varepsilon_{\text{obs},m}$ was specifically chosen for each sample galaxy, and does not come from

a random selection. For this reason, we define a new probability

$$P'[(V/\sigma)_{\text{obs}}, \varepsilon; m_\delta, \sigma_\delta] = \frac{P[(V/\sigma)_{\text{obs}}, \varepsilon; m_\delta, \sigma_\delta]}{\int_0^\infty P[(V/\sigma)_{\text{obs}}, \varepsilon; m_\delta, \sigma_\delta] d(V/\sigma)_{\text{obs}}} \quad (\text{C3})$$

in such a way that

$$\int_0^\infty P'[(V/\sigma)_{\text{obs}}, \varepsilon; m_\delta, \sigma_\delta] d(V/\sigma)_{\text{obs}} = 1, \quad (\text{C4})$$

Figure C1. Logarithmically spaced contours of the likelihood $L(m_\delta, \sigma_\delta)$ as a function of the assumed slope and spread of the δ - ε correlation. The maximum likelihood values are $m_\delta = 0.61$ and $\sigma_\delta = 0.11$.

Figure C2. Same as in Fig. 9, with overlaid magenta lines the contour of the probability $P'[(V/\sigma)_{\text{obs}}, \varepsilon; m_\delta, \sigma_\delta]$ for the best-fitting parameters of Fig. C1. The contours are meant to describe the distribution of the fast-rotating galaxies (blue labels).

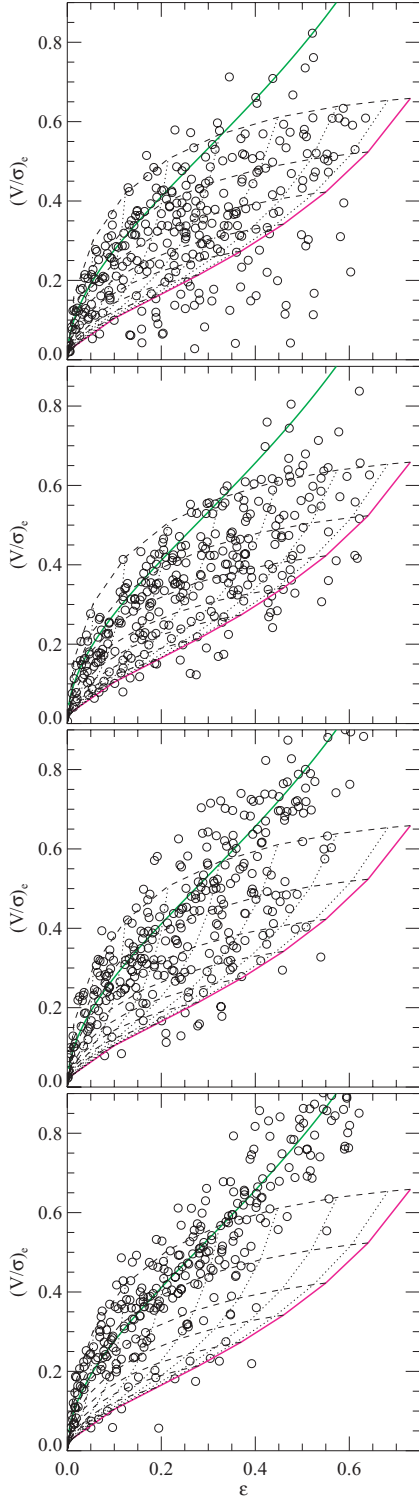

Figure C3. Monte Carlo simulations of the $(V/\sigma, \varepsilon)$ diagram. Top panel: the galaxies follow a relation $\delta = 0.6 \varepsilon_{\text{intr}}$ with added Gaussian intrinsic scatter. Second panel: same as in top panel, but galaxies with $\delta > 0.8 \varepsilon_{\text{intr}}$ are removed. Third panel: at every $\varepsilon_{\text{intr}}$ galaxies are uniformly distributed in the interval $\delta = [0, 0.8 \varepsilon_{\text{intr}}]$. Bottom panel: galaxies are on average isotropic $\delta = 0$, with some added Gaussian intrinsic scatter. Only the second panel resembles the observed distribution of the fast rotators.

or in other words the marginalized probability of observing a galaxy with any given ε is constant. What varies is only the probability of observing a certain $(V/\sigma)_{\text{obs}}$ value at the chosen ε .

To find the best-fitting parameters of our simple model, we then define a likelihood function, which gives the probability (neglecting the effect of measurements errors) of observing the given set of M independent measurements $[(V/\sigma)_{\text{obs},m}, \varepsilon_{\text{obs},m}]$, for the assumed model parameters $(m_\delta, \sigma_\delta)$:

$$L(m_\delta, \sigma_\delta) = \prod_{m=1}^M P' [(V/\sigma)_{\text{obs},m}, \varepsilon_{\text{obs},m}; m_\delta, \sigma_\delta]. \quad (\text{C5})$$

We determine the likelihood only for the fast rotators of the SAURON sample of 48 galaxies, excluding the galaxies NGC 2685, 3156, as they lie in regions of low-number statistics and may not follow the general distribution of the other galaxies, and NGC 4473 for the reasons explained in Section 5.2. This leads to a sample of $M = 36$ galaxies. The contours of the likelihood function (C5) are presented in Fig. C1 and show that the maximum likelihood parameters are $m_\delta = 0.6$ and $\sigma_\delta = 0.1$. Given the very different approach adopted for their determination, the agreement with equation (19) provides a strong confirmation of the observed trend of anisotropy versus ellipticity. The contours of the probability P' for the set of best-fitting parameters are shown in Fig. C2. Although the contours follow the general distribution of the fast rotators, they also display a tail with non-negligible probability at low values of V/σ , where we do not observe any galaxy. This effect is also visualized in the top panel of Fig. C3, where we plot the distribution of values on the $(V/\sigma, \varepsilon)$ diagram, for a simulated set of 300 galaxies. A number of galaxies are predicted by this model to fall below the magenta line.

After some experimentation, we found that the simplest way to reproduce the observations consists of enforcing the upper limit on the anisotropy $\delta \lesssim 0.8 \varepsilon_{\text{intr}}$ in equation (C2). The result of this simulation is shown in the second panel of Fig. C3 and qualitatively resembles the appearance of the observed SAURON $(V/\sigma, \varepsilon)$ diagram. The distribution of the observed galaxies in the $(V/\sigma, \varepsilon)$ diagram suggests that the above condition constitutes a physical zone of avoidance for the existence of the fast rotators. This zone of avoidance may be related to the stability of axisymmetric stellar systems with varying degrees of anisotropy and would deserve further investigations.

In Fig. C3, we present two additional Monte Carlo simulations, under simple assumptions for the galaxy anisotropy. In the third panel we assume, at every $\varepsilon_{\text{intr}}$, a uniform distribution for galaxies in the interval $\delta = [0, 0.8 \varepsilon_{\text{intr}}]$. This distribution is unable to reproduce the observed distribution of the fast rotators on the $(V/\sigma, \varepsilon)$ diagram. Finally, in the bottom panel we assume that galaxies are on average isotropic $\delta = 0$, but we allow for the same Gaussian intrinsic scatter $\sigma_\delta = 0.1$ as in the top panel. This distribution is strongly excluded by the observations. A comparison with the $(V/\sigma, \varepsilon)$ distribution for a much larger and unbiased sample of galaxies would be required to further confirm these results.
